Now when we speak of a lake with two outfalls, I presume we mean one with two natural and permanent outfalls, and in this sense the Læsöskougens Vaud cannot be adduced as an instance at the present day. It is just possible that the lake had a natural outlet at Lesje Værks before the artificial channel was cut, but it is highly improbable, and we should require good traditional or documentary evidence to that effect before we could assume it to be so. Such evidence would probably be very difficult to obtain, and could only be obtained by some person intimate with the Norsk language. Moreover, I judge from the nature of the outfall at this end, that if it were not looked to from time to time, the stream would eventually widen and deepen the channel through the barrier of loose sand and gravel, and finally lower the level of the water by many feet, so as to destroy the outflow into the river Rauma.

I write the above without having previously entered into the subject, and without being able to refer to any information about it. On *à priori* grounds it seems very unlikely that there should exist any lake with two distinct outflows. For in order that such a state of things should exist permanently, either there must be no erosion of the channels whatever, or the erosion must proceed with exact equality, otherwise one stream will augment at the expense of the other, and its eroding power being thus increased, it will more and more tend to sap the supplies of the other stream. The condition of things would, in fact, be that of unstable equilibrium, which could not long continue to exist.

Colonel George Greenwood, who is, I presume, the same as the former active correspondent about this subject, visited this lake last summer, as appears from the entry of his name in the day books. I am not aware that he has since published any opinion, but the lake seems, so far as I can judge, to support his view of the matter.

W. STANLEY JEVONS

THE NEW BIRD OF PARADISE

AT the last scientific meeting of the Zoological Society of London for the past session, I had the pleasure of exhibiting and describing specimens of a new Bird of Paradise recently discovered by Signor Luigi Maria D'Albertis, in New Guinea. As it will be some time before the part of the Society's "Proceedings" containing the record of the business transacted at the meeting on June 17 can be issued, and as I am informed that some knowledge of the existence of this singular bird has been obtained in another quarter, I am anxious to secure to Signor D'Albertis the honour of his discovery by a somewhat earlier publication of such a description and figure as will enable the bird to be recognised by other naturalists.

Drepanornis * *albertisi*, as I have proposed to call this fine bird, in honour of its energetic discoverer, belongs to the long-billed or Epimachine section of the Paradiseæ, and is, perhaps, more nearly allied to *Epimachus* than to any other described form. But it is very distinct from *Epimachus* as regards its long, thin, and much curved bill, shorter legs, and shorter, squarer tail, not to speak of the peculiar tufts of feathers which are characteristic of the male sex only. The general colour of the plumage of the male *Drepanornis* is brown above, and lavender-grey below. The naked rim round the eye, and a bare space at the back of them on each side, are of a bright blue. On each side of the front before the eye rises a short tuft of bright, coppery, metallic green feathers. A large patch of similar scaly feathers covers the chin and throat. Two large tufts of feathers spring from each side of the breast, and form conspicuous ornaments when erected. The upper pair of these peculiar tufts have a mass of brilliant coppery red at the base of their feathers, terminated by a dark band. This metallic colour is only exposed when the plumes are raised. The lower pair of tufts, which are much lengthened, and in a state of repose reach beyond the lower third of the tail, are margined by a splendid purple band. The lower part of the breast is likewise crossed by a narrow band of bright green. The middle of the belly and vent are white, the tail of a nearly uniform pale chestnut.

The above description will give some idea of the special peculiarities of the male *Drepanornis* in full plumage. The female, as is the case in all the true Paradiseæ, is very different in colour, though alike in form. Her plumage is above of a nearly uniform bright brown or rufous, below paler, and crossed on the throat, breast, and sides of the belly, by numerous small irregular black wide cross-bars. The naked space round and behind the eye is coloured bright blue, as in the full-plumaged male. The beak, in the single specimen sent, is still longer than in the male, but this may be an individual peculiarity. The whole length of the male *Drepanornis*, from the tip of the bill to the end of the tail, is about 14 in., that of the wing, from the carpal joint, 6 in., of the tail, from the base, $5\frac{1}{2}$ in., the outer tail feathers being about 1 in. shorter than the middle pair. The bill measures $3\frac{1}{4}$ in. from the front along the curvature, the tarsus $1\frac{1}{4}$ in.

The figure of the *Drepanornis* herewith given is reduced from the lithograph prepared for the "Proceedings" of the Zoological Society, which will form the 47th plate of the volume for 1873, and will be published as soon as the second part is ready.

Signor D'Albertis obtained his examples of this remarkable bird during his recent excursion into the interior of New Guinea, at a place called Atam, which is situated at an elevation of about 3,500 feet above the sea-level in the Arfak mountains. In an account of his journey

* The name originally given at the Zoological Society's meeting of June 17 was *Drepanephorus* (δρεπανηφόρος) *falcem gerens*. (See NATURE, viii. p. 195.) But this term having been previously applied by Sir Philip Egerton to a genus of fossil fishes, I proposed (NATURE, viii. p. 102) to convert the bird's name into *Drepanornis* (δρέπανον *falx et* ὄρνις *avis*).—P. L. S.

recently published in the *Sydney Mail*, he speaks thus of the present species:—

"Among other birds obtained at Atam, I may mention a new species of Bird of Paradise-bird which perhaps may even prove to be of a new genus. I secured only a male and female, which have been transmitted to the Zoological Society of London by the last April mail steamer, and they are unique specimens. It is evidently a very rare bird, for many of the natives did not know it, but others called it *Quani*. The peculiarity of this bird consists in the formation of the bill, and the softness of the plumage. At first it does not apper to have the beauty usually seen in the birds of this group, but when more closely observed, and under a strong light, the plumage is seen to be both rich and brilliant. The feathers that arise from the base of the bill are of a metallic green and of a reddish copper-colour; the feathers of the breast, when laid quite smooth, are of a violet-grey, but when raised, form a semicircle round the body, reflecting a rich golden colour. Other violet-grey feathers arise from the flanks, edged by a rich metallic violet tint; but when the plumage is entirely expanded, the bird appears as if it had formed two semicircles around itself, and is certainly a very handsome bird. Above the tail and wings the feathers are yellowish, underneath they are of a darker shade. The head is barely covered with small round feathers, which are rather deficient behind the ears; the shoulders are of a tobacco-colour, and underneath the throat of a black blending into olive colour; the feathers of the breast are violet-grey, banded by a line of olive, and those of the vent white. The bill is black, eyes chestnut, and the feet of a dark leaden colour. The food of this bird is not yet known, nothing having been found in the stomachs of those I prepared but clear water."

The new Bird of Paradise, *Drepanornis Albertisi*. Upper figure, Male; lower figure, Female.

Besides this Paradise-bird, M. D'Albertis procured from the natives, in the vicinity of Orangeri Bay, on the western coast of New Guinea, opposite to Salawatty, two imperfect skins of a second apparently new species. This is a true Paradisea, nearly allied to the Greater and Lesser Birds of Paradise (*P. apoda* and *P. papuana*), but having the long lateral plumes more of an orange-red, as in *P. rubra*. These skins were likewise exhibited at the Zoological Society's meeting on June 17 last, and the species, in accordance with M. D'Albertis' wishes, was proposed to be called *Paradisea raggiana*, after the Marquis Raggi.

As the collection of birds which contained these two new Paradise-birds only reached me on the morning of the same day as the meeting of the Society, it was not possible to make an accurate examination of all of them before the meeting, and the two Paradise-birds, being the most remarkable among the novelties, were alone described. But I have now had time to examine the whole series carefully, and find that it contains 70 specimens referable to 53 species. Twelve of these (besides the two Paradise-birds) appear to be new to Science, and will be described and named at the first meeting of the Zoological Society in the autumnal session. Besides these novelties there are examples of several other birds recently described by Dr. Schlegel from Rosenberg's collections, and of other rare species.

P. L. SCLATER

ON THE SCIENCE OF WEIGHING AND MEASURING, AND THE STANDARDS OF WEIGHT AND MEASURE *

II.

It has already been mentioned that the gravitation or weight of bodies varies with their density, and the density of the medium in which they are placed. In order to ascertain the true relative weight, as well as the actual weight of standard weights differing in density when they are weighed in air, it is necessary to allow for the weight of air displaced by each. It thus becomes necessary to reduce these weighings to a vacuum, *by deducting from the apparent weight in air the weight of the volume of air displaced by each standard.*

But the weight of a given volume of air is necessarily more or less according to its temperature, the pressure of the atmosphere, and other conditions affecting it; and the following data are requisite for ascertaining the weight of air displaced by each standard.

1. The mean temperature of the air during the weighings.
2. The mean barometric pressure reduced to 32° Fahr. and corrected for the pressure of vapour and of carbonic acid gas in the air.
3. The density of the metal of which each standard weight is composed.
4. The co-efficients of expansion of the metals and of air.
5. The relative weight of each standard.

From data 1 and 2 the ratio of the density of the air to the maximum density of water must be ascertained. This ratio is also affected by the height above the mean level of the sea, and the latitude of the place where the comparison is made, as the force of gravity differs accordingly. But in practice the determination of the weight of air displaced in weighing is easily and quickly effected, either by the more accurate mode of making the computations from the above-mentioned data, with the aid of a logarithmetical formula and tables for reduction of weighings, or approximately by special tables showing the mean weight of ordinary air displaced by standards of various densities. The mean ordinary air taken as the standard air in this country is of the normal temperature of 62° Fahr., the barometer being at 30 inches, with the mercury reduced by computation to the temperature of 32° Fahr., the amount of aqueous vapour in the air being assumed to be two-thirds of the quantity in saturated air, and the amount of carbonic acid contained in it being taken at 0·0004 of its volume.

The actual mode of ascertaining the weight of air displaced by standard weights when compared by weighings in air, will be described more at length afterwards. But some illustrations may here be given of the effect of the difference of density in standard weights, upon their weight in ordinary air. The following 1lb. avoirdupois weights are of the actual form and size:—

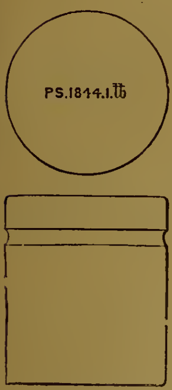

Fig. 1.—Imperial Standard Pound of Platinum.
Diameter = 1·15 inch.
Δ = 21·1572.
Displaces 0·403 grains of air.

Upper Surface of Platinum Standard Pound shown.

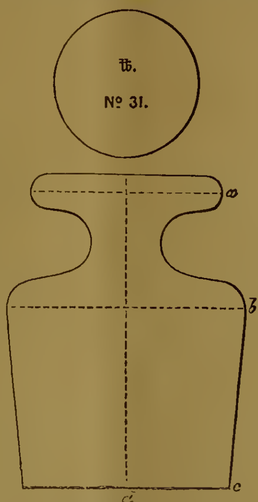

Fig. 2.—Official Standard Pound, Gilt Gun Metal. No. 31.
Size: Diameter at a = 1·25 inch.
" b = 1·65 "
" base c = 1·47 "
Height d = 2·2 inches.
Δ = 8·5144
Displaces 1·001 grain of air.
Upper Surface of Gilt Gun Metal Standard Pound shown.

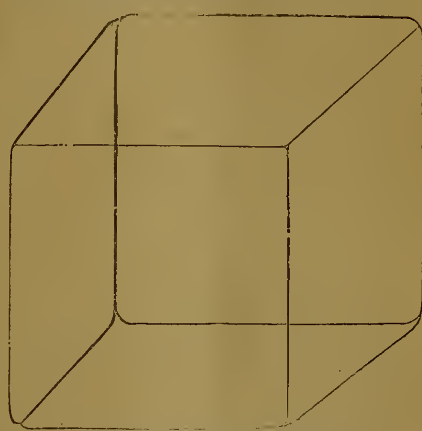

Fig. 3.—Quartz Pound in Standards Department, bearing no mark.
Size = 2·17 inches cube, edges rounded.
Δ = 2·6505. Displaces 3·216 grains of air.

It may here be seen that the difference of air displaced by the imperial standard lb. P.S. (Fig. 1), and the gilt gun metal lb. No. 31 (Fig. 2), is 0·598 gr.; and if they were equal in weight when in a vacuum, No. 31 would be 0·598 gr. lighter in air of the given density. No. 31 is one of the gilt gun-metal secondary standard weights, intended to regulate the weighings in air of all commercial weights. As the primary platinum standard P.S. from its greater density displaced so much less air than ordinary brass and iron weights—the density of cast-iron being about 7·408, and a cast-iron lb. displacing about 1·150 gr. of air—the weight of all the gilt gun-metal lbs., of which No. 31 was one, was referred by Prof. Miller to a theoretical commercial standard lb. of brass of the average density of brass and bronze weights (Δ=8. 143), and thus displacing 1·047 gr. of standard air. This commercial standard lb. denoted as W. was assumed to be of the same weight in a vacuum as P.S., and consequently in standard air P.S. was 0·644 gr. heavier than W.

The standard pound of quartz (Fig. 3) displaces 3·217 grains of air. It was constructed as an auxiliary standard on account of the invariability of quartz, and its apparent

* Continued from p. 270.

weight in air was made intermediate between that of a pound of platinum and a pound of brass, being 0·401 gr. lighter than P.S., and 0·232 gr. heavier than W. in standard air.

As the determination of the density of bodies has thus been referred to the maximum density of an equal volume of water, it was evidently necessary to determine the absolute weight of a normal measure of water at its maximum density, in order to determine the true weight in air of a given volume of any substance, the density of which has been ascertained. It is claimed to be one of the important advantages of the decimal metric system, that this relation may be at once ascertained from the circumstance of the unit of weight, the kilogram, having been determined by its being the weight of a cubic decimetre of pure water at its maximum density. Thus the volume of any body expressed in cubic decimetres, or the measure of capacity of liquids expressed in litres, the litre being the measure of a vessel holding a cubic decimetre of water at its maximum density, when multiplied by its density, at once gives the weight in kilograms; or, if expressed in centimetres, the weight will be given in grammes. There is not the same simple relation between the unit of weight and of volume or capacity in the imperial system, the same definite ratio not being established between the unit of cubic capacity derived from the unit of length and the unit of weight, which is found in the metric system. This relation has therefore been determined experimentally in England from ascertaining the weight of a cubic inch of pure water, and the determination by Sir George Shuckburgh in 1798 was accepted by scientific men in this country, and has been legalised by Statute, by which a cubic inch of water at the temperature of 62° F. weighed in air of the same temperature, with the barometer at 30 inches, weighs, 252·458 grains of brass. From this ratio, the cubic capacity of the standard gallon, containing 10 lbs. weight of water, is declared to be 277·274 inches, and a cubic foot of water is declared to weigh 62·321 lbs. avoirdupois. But this ratio does not agree with that adopted in France, nor indeed with other and different ratios adopted in Sweden, Austria, and Russia respectively, as determined from separate experiments made in each of these countries. As respects the metric system, even assuming the weight of a cubic decimetre of water to be exactly a kilogram according to its theoretical definition, as to which doubts exist, it is only equal to this weight when the water is at the temperature of about 39° F. or 4° C, and when weighed in a vacuum. When of the ordinary temperature (say 62° F.) and weighed against brass weights in ordinary air (say, the barometer at 30 inches), it would weigh not a kilogram or 1,000 grammes, but about 999·012 grammes, the difference being the loss of weight by the weight of air displaced by a cubic decimetre of water. According to the English ratio, the cubic decimetre of water would weigh in air 999·515 grammes. And if the French ratio were applied to our imperial measures a cubic inch of water would weigh 252·336 grains, the capacity of the gallon would be 277·141 inches, and the cubic foot of water would weigh 62·291 lbs. But in point of fact, a new and authoritative international determination of the weight of a standard unit of water is very much needed, in order that its true weight may be satisfactorily ascertained and uniformly adopted in all countries.

II.—*Standards of Imperial Weight and Measure*

The English standard units of weight and length, the pound and the yard, have come down to us from the Saxons. The Mint pound of the Tower of London, which continued to be the legal unit of weight up to the time of Henry VIII., was the old pound of the Saxon Moneyers in use before the Conquest; whilst the earliest recorded standard of length in this country was the yard or *gird* of the Saxon kings, kept at Winchester. King Edgar is recorded to have decreed, with the consent of his Wites, the standard." No change was made by the Normans in the system of weights and measures established in England, and by a statute of William the Conqueror it was ordained that the measures and weights should be true and stamped in all parts of the country, as had before been established by law.

The old Tower pound was the ancient pound sterling of silver, containing 20*s*., each of 12*d*. or pennyweights. It was also divided into 12 ounces, and was thus used as the apothecaries' weight. The Tower pound was less than the Troy pound by 15 dwt., and contained 5,400 Troy grains. It was discontinued by law in the 24th year of Henry VIII., the Troy pound, which appears to have been first introduced into this country from France at the close of the reign of Edward III., being substituted for it. The mark of 8 ounces was $\frac{2}{3}$ of the Tower pound, and was identical in weight with the ancient unit of money weight in Germany, known as the Cologne Mark. The Tower pound was also nearly identical in weight with the ancient Alexandrian pound, the 125th part of the Great Talent of the Ptolemies, from which it was probably derived. The Troy pound is said to have owed its origin to the Arab *rotl* or pound of the Caliph Almamoun, of very nearly equivalent weight, sent as a present to Charlemagne.

The earliest English weight for heavy goods was the merchants' pound, declared in a Statute of Henry III. to be equal to 25*s*., or one-fourth more than the Tower pound. It must thus have been equal to 6,750 Troy grs. Another ancient authority declared the merchants' pound to have contained 15 ounces, and if these were Troy ounces this merchants' pound must have contained 7,200 Troy grs. The merchants' pound seems to have merged insensibly into the avoirdupois pound of 7,000 Troy grs., not later than the time of Edward III. It is certain that commercial pounds nearly equivalent to each of the three weights here specified were largely used in different parts of France and Germany. Our existing avoirdupois pound can be distinctly traced to the time of Edward III.; and there is good ground for believing that no substantial difference has occurred in its weight, or that of the Troy pound, since either of them was first established as a standard in this country.

There can also be little doubt that the length of the English yard has continued unchanged from the earliest times. The standard yard of Henry VII., which is still preserved in the Standards Department, is hardly $\frac{1}{100}$th of an inch shorter than the imperial standard yard, and being an end-standard, it must have lost a little of its original length. The standard weights and measures made in the eleventh year of Henry VII., which are the earliest English standards now known to exist, are all declared to have been taken from the older standards of the Exchequer, as were also the later standards of Queen Elizabeth, which continued to be the legal standards of the country up to the year 1824. Although there is no direct evidence of the origin of the Saxon yard, it is highly probable, from its length agreeing very nearly with that of double the natural cubit (of about 18 English inches) and from its third part, the foot, being very nearly identical with the ancient Egyptian and Greek foot, that these two English unit measures of length owe their origin to the cubit of a man, the earliest known standard measure of length recorded in ancient history.

The Troy pound was the standard unit of weight in this country from the time of Henry VIII. up to the year 1855, when the imperial pound avoirdupois was made the legal standard of weight. The actual primary units of imperial weight and measure are now the standard pound avoirdupois and the standard yard in the custody of the Warden of the Standards, and deposited at the Standards Department, Old Palace Yard, Westminster. They were constructed under the superintendence of the Standards Commission, appointed in 1843 for the restoration of the standards of weight and measure which had been

or Council, that "the measure of Winchester should be placed in the custody of the Clerk of the House of Commons, and were destroyed by the burning of the Houses of Parliament on October 11, 1834. The members of this Standards Commission had previously given their services as a preliminary committee, having been appointed in 1838 to consider the steps to be taken for restoring the standards, the Act of 1824 (5 Geo. IV. c. 74), under the authority of which the lost standards had been legalised, having directed that, in the event of their loss or destruction, new standards should be constructed in accordance with provisions contained in the Act, by reference to an invariable natural standard.

These provisions were as follows:—In regard to the Standard of Weight, it was recited in § 5 of the Act, that a cubic inch of distilled water, weighed in air against brass weights, at the temperature of 62° Fahr. the barometer being at 30 inches, had been determined by scientific men to be equal to 252·458 grains, of which the Standard Troy pound contained 5,760; and if this Standard were lost or destroyed, a new Standard Troy pound was to be constructed, bearing the same proportion to the weight of a cubic inch of water, as the Standard pound bore to such cubic inch of water.

It will thus be seen that the new unit of weight was declared to be dependent upon the new unit of length, it being based upon the capacity of the cubic inch, or the cube of the thirty-sixth part of the Standard yard.

With respect to the Standard unit of length, § 3 of the Act recited that the Imperial Standard yard, when compared with a pendulum vibrating seconds of mean time in the latitude of London, in a vacuum at the level of the sea, had also been determined to be in the proportion of 36 inches to 39·1393 inches, and it was provided that if lost or destroyed, a new Standard yard should be constructed bearing the same proportion to such pendulum, as the Imperial Standard yard then bore to it.

After long deliberation, the Committee made a very full Report, dated December 21, 1841, and declared their opinion that the several elements of reduction of the pendulum experiments referred to in the Act of 1824, were doubtful or erroneous. It was evident, therefore, that the course prescribed by the Act would not necessarily reproduce the Standard yard. It appeared also that the determination of the weight of a cubic inch of water was still doubtful, differences being found between the best English, French, Austrian, Swedish and Russian determinations amounting to about $\frac{1}{1200}$ of the whole weight, whereas the results of the mere operation of weighing might be determined within $\frac{1}{1000000}$ of the whole weight. The Committee were fully persuaded that with reasonable precautions, it would always be possible to provide for the accurate restoration of Standards by means of material copies which had been compared with them. And they had ascertained that several measures existed which had been most carefully compared with the former Standard yard; and several weights, which had been most accurately compared with the lost Standard pound; and by the use of these, the values of the original standards could be restored without sensible error.

They recommended that no change should be made in the values of the primary units of the weights and measures of the kingdom, or in the meaning of the names by which they were commonly denoted; that the construction of the Standards be entrusted to a Committee of scientific men, under certain instructions contained in the Report, and by comparison with the most carefully selected specimens; that the Parliamentary standard of length be one yard, there appearing no sufficient reason for departing from the length hitherto adopted for the standard; and that the Avoirdupois pound be adopted instead of the Troy pound as the Parliamentary standard of weight, the avoirdupois pound being invariably known and generally used, and the Troy pound being wholly unknown to the great mass of the British population, and comparatively useless. They also recommended that no new specific standard of capacity be established, the unit of capacity, the gallon, being continued to be defined by its containing 10 lbs. weight of distilled water, as specified in the Act of 1824.

Many other important recommendations were also made by the Committee in relation to the official Secondary Standards, and the verification and legalising of local Standards for the use of Inspectors of Weights and Measures throughout the country, and for the Colonies, in order to secure the requisite uniformity in commercial weights and measures, and their accordance with the scientifically constructed primary standards.

For more effectually carrying out these recommendations for the construction of the new Standards, the Standards Commission was appointed on June 20, 1843, and continued their labours until 1854, their definitive Report being dated on March 28 in that year.

The preliminary Committee was composed of the following scientific men:—G. B. Airy, Astronomer Royal, Chairman (now Sir G. B. Airy, K.C.B., and President of the Royal Society); F. Baily, V.P.R.S.; J. E. D. Bethune; Davies Gilbert, V.P.R.S.; J. G. S. Lefevre (now Sir J. G. S. Lefevre, K.C.B.); J. W. Lubbock (afterwards Sir J. W. Lubbock, Bart.); Rev. G. Peacock, F.R.S. Dean of Ely and Lowdian Professor of Astronomy; Rev. R. Sheepshanks, F.R.S.; Sir J. F. H. Herschel, Bart. With the exception of Mr. Davies Gilbert, who died in the meantime, all these scientific men continued their services as members of the Commission for constructing the new Standards. The Marquis of Northampton, P.R.S., Lord Wrottesley, F.R.S., and Prof. W. H. Miller were also appointed members of the Commission. On the death of the Marquis of Northampton, the name of the Earl of Rosse, his successor as President of the Royal Society, was added.

H. W. CHISHOLM

OREODON REMAINS IN THE WOODWARDIAN MUSEUM, CAMBRIDGE

IN addition to the valuable collection of recent skeletons lately given by Lord Walsingham to the University of Cambridge, he also presented a series of mammalian remains from the Miocene deposits of the Mauvaises Terres in Nebraska. These were, fortunately, for the most part brought to England in masses of the original rock, and have therefore had the great advantage of Mr. H. Keeping's care and skill in developing them from the matrix. His long-continued labour has resulted in the most interesting collection of fossils referred to in this notice, and now deposited in the Woodwardian Museum. Professor Hughes has entrusted me with the examination and determination of the remains, and has afforded me every possible assistance. The species revealed, some of which may possibly require the establishment of a new genus, at any rate appear to be new to science, and much larger than any hitherto described in America. We have thought that, pending the preparation of a complete description, your readers would be interested in a general account of the fossils; and especially it has been thought desirable that an account of the skull and dentition should be given in as simple a form as possible; for I have not yet seen any description of the skull other than the complete one of Prof. Leidy. At any rate, fresh interest will be excited in the Oreodontidæ now that so splendid a series of remains can be seen in an English Museum.

A summary of our fossils may be thus given:—

1. A large nearly complete skull, with lower jaw attached; the zygomatic arches being, however, almost destroyed.

2. The greater portion of a large skull preserving very completely one zygomatic arch with posterior crest.

3. Another skull of the same species showing the part anterior to the bifurcation of the sagittal crest.

4. Another large skull of the same species, wanting the greater part of the face.

5. A nearly complete skull of another species.

6. The greater part of two skulls of *Oreodon Culbertsoni* (the original and typical species), smaller than any of the above.

7. Half of the frontal region of an individual larger than any of the others.

8. Casts of the brain of a large and of a small species, with determinable parts of bones attached.

9. Many pieces, more or less complete, chiefly parts of upper and lower jaws with teeth, including a number which show the canine and incisor teeth.

10. Portions of limb bones, and a number of vertebræ.

Besides these, the collection includes Carnivorous, Rodent, and other very interesting remains.

"The deposits of the Mauvaises Terres," says Prof. Leidy, "are remarkable for the great quantity of fossil remains of mammals and turtles they have yielded without further exploration than picking them up from the surface of the country. Detached from the neighbouring soft and readily disintegrating rocks, the fossils lie strewn about, and have often attracted the attention of the least curious of those who have traversed the district. Many of the loose fossils have gradually been collected by travellers and others, so that few of a conspicuous character, I am told, now remain. Of those collected, by far the greater part have been submitted to my investigation, and these have amounted to the enormous quantity of between three and four tons in weight." The first description of fossils from the Mauvaises Terres, was by Dr. Prout, who, in 1846 and 1847, described a jaw of a large animal supposed to be a Palæotherium, in the *American Journal of Science and Art*. Gradually specimens came to light, many of which were described by Prof. Leidy, who collected and completed his descriptions in 1852, when he published, in the Smithsonian Contributions, "The Ancient Fauna of Nebraska," of 126 pages, and 24 splendid plates. In succeeding years the Mauvaises Terres were further explored by Dr. David Dale Owen, Dr. John Evans, and Dr. F. V. Hayden, who brought to Philadelphia large collections of fossils. Altogether Prof. Leidy supposes that he has seen entire skulls or portions of skulls of about 500 individual Oreodonts, a very large proportion of which belong to one species, *Oreodon Culbertsoni*. In 1869 the results of his twenty years' labour were published as the seventh volume of the second series of the "Journal of the Academy of Natural Sciences of Philadelphia," under the title of the "Extinct Mammalian Fauna of Dakotah and Nebraska," 472 pages, and 29 plates, large quarto. This great work includes also a synopsis of the entire mammalian remains of North America, with the most complete references and the author's valuable critical opinions. The interest is not merely in the artiodactyle ungulates, but also in the perissodactyles, including the famous Hipparion and Anchitherium, as well as the Rhinoceros, Machairodus, Mastodon, and Edentate remains. Quite recently Prof. Marsh has described a new medium-sized species of Oreodon in the current number of the *American Journal of Science and Art*.

The family Oreodontidæ is characterised by the possession of an elongated massive skull, of which the portion in front of the articulation of the lower jaw constitutes more than three-fourths. The upper surface slopes gradually from behind forwards. Posteriorly is a high sagittal crest ($1\frac{1}{2}$ in. at the greatest height in large species), reaching far back, so as to project on a level considerably behind that of the occipital condyles. The crest is flanked by large and wide temporal fossæ, their floor being chiefly formed by the squamous bone, which is internally strongly convex, and bears a blunt ridge proceeding from behind forwards, downwards, and outwards. The sagittal crest bifurcates anteriorly to form the postero-lateral sides of a nearly flat lozenge-shaped frontal region, whose lateral angles overarch the completed bony orbits. The upper surface of the face is terminated by elongated convex nasals, which extend, I think, quite to the level of the front of the premaxilla, and project further in the middle line than at the sides. The nasal cavities are very large, high at the anterior opening, and do not open laterally on the face near the orbit. They have complicated turbinals. The frontal region is alternately gently convex and concave, being more convex near the lateral angles. The frontals have, near the middle line on each side, a considerable supra-orbital foramen, appearing at about the level of the posterior boundary of the orbit.

On the lateral aspect of the skull there is first to be noticed the lateral occipital crest which extends outwards and backwards, as the outer margin of the post-occipital fossa, which varies in size. It then bifurcates, giving an inferior branch continuing the margin of this fossa, and a lateral branch which passes far outwards, bounding the great temporal fossa. This ridge rises higher as it recedes from the occipital region, and external to the articulation of the lower jaw developes into a curved crest, which is remarkably large and thick in one specimen. Further forward this crest does not exist. The widest part of the skull is just in front of this; in one of our species the width at this point is twice as great as the distance from the occipital to the orbit. The zygomatic process of the squamosal comes forward to the under part of the orbit, and is received into a long concavity of the malar. The latter passes above this process, to join the post-orbital process of the frontal, and bound the large oval or circular orbit. The malar is often of great vertical depth, and joins a prominence of the maxillæ above the alveoli of the posterior molars. Inside and above this elevation, the lachrymal occupies a considerable space on the face, and has an antorbital fossa of varying size. Anteriorly the face continues comparatively high, generally convex, and nearly vertical.

The base of the skull presents the occipital condyles, which have their anterior and posterior portions obliquely bent upon each other at an acute angle; they approach very close to one another in the median line below. The basi-occipital has a strong raised median ridge, which gradually dies away on the basi-sphenoid. The basi-cranial axis is set at an angle of about 40° to the palatine axis. Externally there is a large nipple-shaped post-glenoid process of the squamosal (the transverse diameter being the greater). Immediately on its inner side is a large auditory bulla, somewhat compressed; and applied to its external surface, and at the same time nearly touching the post-glenoid process is a long and strong paroccipital. The external meatus opens obliquely upward in front of the paroccipital.

Between the teeth, the palate is of almost uniform width, is regularly concave, and smooth. It extends for some distance behind the molar teeth, being narrowed; and has a concave posterior margin of different form in the various species. The pterygoid continues the lateral part of the concavity to the alisphenoid region.

The horizontal ramus of the mandible is of moderate height, each half being separated slightly from the other in the specimens. The symphysis is considerable, and shows serrated sutures. The anterior end of the mandible is very little diminished in height, has less of the spatulate form than ordinary ruminants, and is somewhat expanded in consequence of the size of the canines. The rami are very nearly parallel throughout their whole extent. The ascending ramus is high, with a small coronoid process, and a transversely elongated condyle.

The dental formula is—

$$i. \frac{3-3}{3-3} \; c. \frac{1-1}{1-1} \; p.m. \frac{4-4}{4-4} \; m. \frac{3-3}{3-3} = 44.$$

In the middle line above there are six small somewhat chisel-shaped incisors, increasing in size from within outwards. Next succeeds a large curved conical canine, flattened on its external aspect, and bearing a slight median longitudinal groove. There are seven teeth in the molar series, of which the first four appear to be premolars. These teeth present characters common to most ruminant genera, the premolars showing one double crescent, and the true molars two double crescents; the convexity of the crescents being turned inwards as in the upper jaw of all ruminants. They are very square in general shape, and the crescents are very convex. The junction of the anterior and posterior crescents externally is raised into a strong column, and a similar column projects as a third lobe on the posterior molar.

In the lower jaw eight teeth appear in front; the six middle ones of about the same size as the incisors of the upper jaw, but more cylindrical. The extreme tooth on each side, homologically a canine, is considerably larger and more chisel-shaped. The upper canine bites immediately behind this tooth; and behind this again is a long curved caniniform tooth similar to the canine of the upper jaw. Three premolars and three true molars succeed. They are generally similar to those of the upper jaw, but have the convexities of the crescents turned outwards. Throughout the series of teeth there is no diastema, except just as much as will allow the canine teeth to fit compactly above and below.

The following are, roughly, the dimensions of the large skull No. 1:—Length on upper surface, $13\frac{1}{2}$ or 14 inches; height posteriorly $8\frac{1}{2}$ inches: anteriorly, nearly 6 inches; length of lower jaw, $10\frac{1}{2}$ inches; length of molar series of upper jaw, 6 inches.

A brief comparison with some other skulls will assist in giving an idea of the affinities of the Oreodonts. The Peccary presents perhaps the greatest number of resemblances. The sagittal ridge and frontal surface are somewhat alike, but the sagittal ridge is much longer and higher in Oreodon. The part of the squamosal (with the high crest) posterior to the glenoid cavity is similar, but not nearly so elevated or so widely diverging from the middle line. The supra-orbital foramen is on the level of the anterior, and not the posterior of the orbit. The post-occipital fossa and the condyles are very much alike; so is the narrowing of the palate behind the molars; but the palate is wider and not so long proportionally in Oreodon. The posterior edge of the mandible is similar.

But the differences between Oreodon and the Peccary are many and important; the characters of the teeth are very different: the Peccary has a large diastema; the mandibular rami are not parallel, the nasal cavities are smaller in proportion; there is no lachrymal fossa; the orbit is incomplete; there is scarcely any post-glenoid process of the squamosal.

The pig exhibits somewhat more likeness to Oreodon in the relations and size of the par-occipital and the auditory bullæ; but differs still more importantly in the wide separation of the two temporal fossæ by the intervening flat parietals.

The Camel agrees with Oreodon in the large size and close proximity of its temporal fossæ, which are separated by a sagittal crest, but the latter is low, and the floor of the temporal fossa is exceedingly convex. There are vast differences in the face, teeth, mandible, and auditory bullæ.

In the ordinary Ruminant, as the sheep, it is the face which presents most resemblances to our specimens. These consist in the shape of the nasals, the nearly vertical maxillæ, the complete orbits, the antorbital fossa of the lachrymal, the Ruminant molars, and the form of the palate between the molars. But the posterior part of the skull is very unlike. Even in the molar teeth, while the type is the same there are considerable differences which will be hereafter fully described.

The Llama is much less like Oreodon than the camel is.

The casts of brains and the limb and trunk-bones and vertebræ promise to afford very interesting matter, but I have not yet made a careful examination of them.

G. T. BETTANY

ASTRONOMICAL ALMANACS,

A COMPARATIVE HISTORY OF THE "CONNAISSANCE DES TEMPS," THE "NAUTICAL ALMANAC," AND THE "JAHRBUCH" OF BERLIN.*

I.—*The "Connaissance des Temps" of Picard and Lefebvre.*

IN 1666 a celebrated bookseller of Paris, Jean de la Caille, at the sign of the "Fontaine d'or," in the Rue Jacob, published, at his own expense, the "Astronomical Ephemerides" of Hecker, the Astronomer of Dantzig. These Ephemerides were calculated on the observations of Tycho Brahe and Kepler, according to the rules given in the Rudolphine tables—tables constructed at the expense of Rudolph II., Emperor of Germany, by Tycho Brahe, Kepler and himself. Their title was, "Johannis Heckeri Motuum Cælestium Ephemerides, ad anno 1676, ad annum 1680, ex observationibus correctis nobilissimorum Tychonis Brahei et Johannis Kepleri. Hypothesibus Physicis, tabulisque Rudolphinis ad meridianum Uraniburgicum in freto Cymbrico."

These tables gave for the meridian of Uranibourg (island of Heven, between Copenhagen and Elsinore)—which derived considerable importance from the immortal observations of Tycho Brahe—and for each day the longitudes and latitudes of the sun, of the moon, of Mercury, Venus, Mars, Jupiter, and Saturn; the longitudes in degrees and minutes for the planets and the sun, in degrees, minutes, and seconds for the moon; the latitudes in degrees. They contained, moreover, an announcement of the eclipses of the sun and of the moon for the whole period indicated, and a table of geographical co-ordinates (latitude and longitude reckoned from Uranibourg) of the principal towns.

These Ephemerides, the best that then existed, stopping at the year 1860, Picard, the creator of exact astronomy, resolved to continue them. But on account of a voyage which King Louis XIV. was about to undertake, and during which the work which Picard proposed might be useful, the French astronomer decided to advance by a year the date of his publication, and to commence with the year 1679.

The Ephemerides of Picard are thus titled:—"La Connaissance des Temps ou Calendrier et Ephémérides de lever et coucher du soleil, de la lune et des autres planètes, avec les éclipses, pour l'année 1679, calculées sur Paris, et la manère de s'en servir pour les autres élévations†; avec plusieurs autres tables et traités d'astronomie et de physique, et des Ephémérides de toutes les planétes en figures."

This work contains the following information:—1. The time, almost to the minute, of the rising and setting of the sun and moon at Paris, for every day of the year. 2. The time of the rising and setting of the sun (every fortnight) and of the moon (every ten days) for Calais, Paris, Lyon, and Marseille. From these tables the preceding time could be calculated for every point of France. 3. Announcement of eclipses of the sun and moon. 4. The time of the passage of the moon across the meridian and the right ascension of the sun for every day of the year. We have thus the time of the tide. Be-

* Translated from *La Revue Scientifique*, July 19.
† The word *élévation* is synonymous with *latitude*.

sides, the solar dials could be used to obtain the hour during the night by the shadow of the moon; and indeed the time at night could be obtained by observation of the fixed stars. The same table contains the value of the equation of clocks and pendulums, what we now call the "equation of time." 5. A summary of the movements of all the planets for the year, containing little but an indication of the epochs when they were visible and of the constellations through which they passed. 6. A plate in which the preceding data were graphically traced. 7. A table of the latitudes and longitudes (adjusted to the meridian of Paris) of the principal cities of France. 8. An appendix, relating to physical questions, containing an account of the winds which prevailed in Paris for every day of the preceding year, and an exact account of barometric indications for the same period.

In 1680, Picard completed his volume by the following additions:—A note on the inquiry into longitudes (*recherches des longitudes*) by means of clocks and pendulums; a table of lengths of the pendulum corresponding to an increasing number of vibrations per second, and intended for the regulation of clocks; a table of declinations of the sun for each day (by degrees and minutes); and lastly, a table indicating the weights of the unit of volume (a cubic foot) of different substances.

These Ephemerides, although less complete, so far as pure astronomy is concerned, than those of Hecker, were, however, superior to them from a practical point of view, by the substitution of the right ascension of the sun and moon for the longitude and latitude of these bodies; it is, in fact, the right ascension and declination which are directly useful to astronomers.

Picard, who published the "Connaissance des Temps" at his own expense and his own risk, was naturally interested in the success of his work. Thus, after having sought to satisfy the wants of astronomers and mariners, he added to this publication a list of the days on which the posts to the various towns of France set out from Paris. The custom of adding to the astronomical tables physical or statistical data altogether foreign to astronomy, has been continued to the present time in the "Annuaire du Bureau des Longitudes."

Still the great labour required in editing these Ephemerides soon tired the Abbé Picard, who tried to find a successor. There was then at the college of Lisieux, at Paris, a professor of rhetoric named Pierre, who was a good astronomer, and on that account was intimate with all the astronomers of his time. The learned Abbé asked him one day if he knew any one capable of assisting him, and afterwards of carrying on the "Connaissance des Temps;" Pierre proposed Jean Lefebvre, weaver at Lisieux, who, in the intervals of leisure which his work allowed him, amused himself by reading some books on astronomy, and was familiar enough with that science to be known to Pierre, originally of the same town: he had sent the latter, among other things, calculations of eclipses which quite agreed with observation. Pierre and Picard then asked Lefebvre to calculate a table of the passage of the moon across the meridian, and this having been accurately performed, they offered him an academician's annuity to come to Paris and continue the "Connaissance des Temps." We owe to his calculations the volumes from 1684 to 1702. Profiting by the new tables of the equation of the sun of Picard and Cassini, he was able to calculate the "Connaissance des Temps" with more accuracy than had ever been done before.

To Lefebvre also are due several additions and modifications. Thus in 1686 he added a table of the exact positions of the planets, the sun, and the moon for every ten days; in 1690 he gave the immersions and emergences of the first satellite of Jupiter; in 1691 maxims in reference to the movement of a ship, a list of ports and coasts, &c. In 1692 he added a table of refractions from 0° to 90° of apparent height, calculated to a minute up to 48° and to a second from 48° to 90°, as well as a value of the declination of the needle according to the observation of La Hire.

In 1693 Lefebvre, having left Paris to take part in the geodetic operations of Picard, one of his colleagues of the Academy, Lieutaud, edited the *Connaissance des Temps* in 1693 and 1694; but on his return he resumed the editorship, and continued it without interruption till 1702.

At that time, in consequence of an incident curious enough to bear relation, the publication of the *Connaissance des Temps* was taken up by the Academy of Sciences.

The son of De la Hire, a very popular academician, who had considerable influence among his colleagues, published, for 1701, a collection of Ephemerides intended to rival those of Lefebvre, in which he said, "I hope, at least, that there will not be found here errors (*éloignements*) of calculation so great as are seen in certain popular and much praised Ephemerides," &c. Wounded to the quick by such a reproach, altogether untrue, Lefebvre wrote in the preface of the *Connaissance*, for 1701, "I cannot avoid replying to the invectives of a certain small novice [De la Hire *fils*], supposed author of an annual Ephemerides published a short time ago. This new author, filled with a spirit of vanity, presumption, and falsehood . . . We reply to this youthful novice . . ."

De la Hire, himself, was not spared. At this uncouth reply the enemy's camp winced, and resolved on revenge; success was easy, for Lefebvre was by no means a general favourite. Little by little the meetings of the Academy were rendered insupportable to him, and when he had absented himself for a certain number of meetings, his name was struck out of the lists of that body. Deprived of his Academician's pension, Lefebvre could no longer continue the *Connaissance des Temps*. The Academy then took possession of the publication, which became a public undertaking; so that the volume of 1702, instead of being, like the previous ones, dedicated to the king, is published "by order of the Academy of Sciences." The old title is changed, and it is simply called "Connaissance des Temps, pour le Méridien de Paris."

(*To be continued.*)

NOTES

In reference to the meeting of the British Association at Bradford, the Reception Room will be opened on Monday, September 15, at 1 P.M., and on the following days at 8 A.M., for the issue of tickets to members, associates, and ladies, and for supplying lists and prices of lodgings, and other information, to strangers on their arrival. No tickets will be issued after 6 P.M. On and after Monday, September 15, members, and persons desirous of becoming members or associates, or of obtaining ladies' tickets, are requested to make application in this room. In the Reception Room there will be offices for supplying information regarding the proceedings of the meeting. The "Journal," containing announcements of the arrangements for each day, will be laid on the table on Wednesday, September 17, and the following mornings, at 8 A.M., for gratuitous distribution. Lists of members present will be issued as soon as possible after the meeting, and will be placed in the same room for distribution. The first general meeting will be held on Wednesday, September 17, at 8 P.M. precisely, when Dr. Carpenter, LL.D., F.R.S., &c., will resign the chair, and the President Elect will assume the presidency, and deliver an address. On Thursday evening, September 18, at 8 P.M., a Soirée; on Friday evening, September 19, at 8.30 P.M., a Discourse; on Monday evening, September 22, at 8.30 P.M., a Discourse; on Tuesday evening, September 23, at 8 P.M., a Soirée;

on Wednesday, September 24, the concluding General Meeting will be held at 2.30 P.M. We omitted to mention in last week's number that the President of Section D, Biology, is Prof. Allmann, M.D., F.R.S.

SIR HENRY RAWLINSON has received a letter dated Khartoom, July 2, from Sir Samuel Baker. Sir Samuel expresses a hope that he will be in England in September. In reference to the oneness of Lakes Tanganyika and Albert Nyanza, he says:—"The envoys sent by M'tése all assured me that the Tanganyika is the M'wootan N'zizé (Albert Nyanza) and that Ujiji is on the eastern border; that you can travel by boat from Ujiji to the north end of the Albert Lake; but you must have a guide, as some portions are very narrow and intricate. From my experience of the high-water grass, I should expect islands and floating vegetation in the narrow passes described. I am by no means fond of geographical theories, but the natives' descriptions were so clear that I accepted as a fact that the Tanganyika and Albert Lakes are one sheet of water, with marshy narrow straits overgrown with water grass, through which you require a guide."

THE Session of the British Medical Association in London during the last week seems in all respects to have been most successful: a great many papers were read, and a great quantity of pleasuring hurried through. Many of the papers were valuable from a medical point of view, and some of importance even from a general scientific standpoint. This week we give a short abstract of Dr. Sanderson's address.

AT the annual general meeting of the Royal Botanical Society, on Monday, the Council congratulated the Fellows on the fact that since the last anniversary meeting the progress which had characterised the operations of the society during the last few years had been maintained. The number of new Fellows elected during the year was 114, being an increase of ten above that of last year; few resignations had occurred. The total number of Fellows and members at the present time was 2,502, the largest on the books of the society since its commencement. The total amount received in subscriptions was 250*l.* in excess of that of last year, and considerably above the average of the last few seasons. From the auditor's report it appeared that the total receipts for the year, including the balance of 529*l.* from the previous year, amounted to 13,434*l.* 6*s.* 11*d.*, and the payments, exclusive of the balance in hand, 2,170*l.* 9*s.* 4*d.*, to 11,263*l.* 17*s.* 7*d.* The report of the secretary was also read, and was equally satisfactory with the other reports. The Council for the next year was elected by ballot.

PROF. G. SCHWEIZER, Director of the Moscow Observatory, died on July 5, after a long illness.

THE death of Sir Francis Ronalds in his 86th year, at Battle, in Sussex, has just been announced. Sir Francis was well known, many years ago, for his experiments in electricity. In 1823 he published a pamphlet containing an account of some of his experiments, and explaining, with the help of illustrations, his plan of an electric telegraph. He had erected in his own garden, first at Highbury and then at Hammersmith, a number of poles supporting eight miles of wire, and through this wire he sent his messages. Each message was read at the further end by means of two needles moving on a dial plate, a plan much the same as that which afterwards came into general use. The spark in his telegraph system was however created by an electrical machine, and not, as in existing systems, by a galvanic battery. In recognition of the value of his discovery, the Government bestowed on him the honour of knighthood in 1870, when the same mark of appreciation had been conferred on Sir Charles Wheatstone for his improvement of the telegraph. Sir F. Ronalds superintended for a short time the Meteorological Observatory at Kew on behalf of the British Association, and the Government conferred upon him a small pension for his services to Science. For some years he lived in the north of Italy, studying the works of Italian writers on electricity. Lately he was engaged in his home at Battle in preparing a catalogue of the published books and papers on electrical science, which we believe is quite ready for print, and will be of great value to students.

To the notice which appeared some few weeks back stating that the large female Octopus had deposited a quantity of spawn on the rock-work of her tank, we have now to add the still more interesting intelligence of the successful development and escape of the perfected embryos. It will be remembered that the first of these eggs were deposited on June 19, and as the earliest arrivals of the young Octopods into the outer waters of their tanks took place on Friday the 8th inst., we have just eight weeks as the period of incubation. Mr. Saville Kent, having personally witnessed the congress of the two sexes in April last, we are also in a position to record an almost similar period occupied during the process of gestation, and which together constitute an important addition to our previous knowledge of the habits of the Cephalopoda. Since Mr. Saville Kent's resignation of the Curatorship, the Brighton Aquarium has unfortunately lost the older and tamer example of the two porpoises, commented upon by that gentleman in NATURE for July 17, as also the unique specimens of the Sturgeon and John Dorée, which have likewise received a share of attention from the same pen in the pages of this journal.

THE Lords of the Committee of Council on Education are about to appoint a keeper of the Natural History Department of the Edinburgh Museum of Science and Art. The salary will be 350*l.*, rising to 450*l.* per annum. Candidates should apply to the Secretary, Science and Art Department, South Kensington.

THE German African Exploration Society has received a despatch, dated July 1, announcing the arrival of Professors Bastian and Goeschen at Cabinna Clougd, for which place Dr. Guesfeldt had started on June 28 from Sierra Leone. Dr. Falkenstein, Dr. Anatoin, physician, and Herr Linder, engineer, are hourly awaiting, at Berlin, further intelligence, on receipt of which they leave to join the expedition.

Xanthorrœa australis, one of the grass gum trees of Australia, is coming into flower for the first time in Europe, in the succulent-house at Kew. There is also a fine plant of *Agave jacquiniana*, removed to the palm-house for the sake of space, which is now in full flower.

DR. PETERMANN has sent us advanced sheets of some of the articles to appear in the forthcoming number of his *Mittheilungen*. One of these gives an account of the *Polaris* Arctic Expedition under the unfortunate Capt. Hall, and points out the main scientific results, which Dr. Petermann rightly regards as of the highest importance. He animadverts with considerable severity on the conduct of the English for the last nine years with regard to Arctic exploration; we, he says, having during that time endeavoured to depreciate the efforts of others, while we ourselves have done nothing. Even the expedition of the daring Hall, he declares, we sneered at when it set out, and since its fate was known, have spoken slightingly of the results. We must acknowledge that Dr. Petermann's taunt as to our inaction during the last nine years in the direction of Arctic exploration is to some extent justified by facts; that inaction, however, is not due to the apathy of English men of Science but to the parsimony of the British Government. We have done much in the way of private effort for discovery, but no amount of private effort is equal to the fitting out of an adequate Polar Expedition. It is, we believe, the earnest desire of all classes that Government should provide the means of enabling this country to take that foremost part in Arctic exploration which was formerly hers without dispute, by fitting out a thoroughly equipped expedition, an expedition which should have for one of its

aims the finding of the Pole. As to Captain Hall's expedition, so far as we are aware, the high value of its results has been everywhere in this country gratefully acknowledged, as well as the indomitable bravery and enthusiasm and high intelligence of the leader; one of its most important results, for which all men of Science must be thankful, is that it has left the most practicable path to the Pole no longer questionable. That the *Polaris*, however, was ill suited for ice-navigation, and that there was a want of that thorough discipline on board, without which no expedition of the kind can hope to be perfectly successful, we still maintain is borne out by what was elicited during the official investigation. We sincerely hope with Dr. Petermann that the magnanimity and liberality of the American Government will be the means of putting an end to the "mere talk of Englishmen," and of inducing our Government at last to set about organising on the most liberal scale an expedition to leave our shores in the spring of 1874. Other papers in the forthcoming number are "With the Russian Army against Khiva," being two letters to Dr. Petermann from Lieut. Hugo Stumm, of the Westphalian Hussar Regiment, and a paper by Dr. D. Sievers, dated Tiflis, May 7, full of geographical information of great importance. The same number will contain the conclusion of Baron von Richthofen's account of his travels from Pekin to Sz'-tshwan.

THE last issued number (vii.) of Petermann's *Mittheilungen* contains the conclusion of Ernest Marno's Travels in High Sennaar; the Results of the Observations made during the voyage of the *Albert* in November and December last, by Prof. Mohn, Director of the Norwegian Meteorological Institute; and a well-constructed map of the Chinese Province of Kuang Tung, from native and foreign authorities, by Dr. Hirth, with accompanying description.

PROF. AGASSIZ, in his address to the students, at the opening of the American School of Natural History, on Penikese Island, said:—"Our chief work will be to watch the aquarium. I want you to study principally marine animals. The only way to do that properly, is to have them alive by your side. In a very few days I shall place at your disposal a series of these appliances. I have ordered one for every person admitted to the school, so that each of you will have means to make these investigations. I have never had, in my own laboratory, better opportunities for work than I place at your disposal. Our way of studying will be somewhat different from the instruction generally given in schools. I want to make it so very different, that it may appear that there is something left to be done in the system adopted in our public schools. I think that pupils are made too much to turn their attention to books, and the teacher is left a simple machine of study. That should be done away with among us. I shall never make you repeat what you have been told, but constantly ask you what you have seen yourselves." The following men of science will, it is said, assist Prof. Agassiz in the conduct of his new charge:—Dr. Burt G. Wilder, of Cornell; Dr. A. S. Packard, of Peabody Academy of Science, Salem; Count Pourtales, of the Coast Survey; Prof. Waterhouse Hawkins, of England; Paulus Roetter, artist of the Museum at Cambridge; Prof. Mitchell, of the Coast Survey; Prof. Joseph S. Lovering, of Harvard University; Prof. F. W. Putnam, of Peabody Academy of Science, Salem; Prof. N. S. Shaler, of Harvard; Prof. Arnold Guyot, of Princeton, N. J.; Prof. Brown-Séquard.

ACCORDING to the *Melbourne Argus*, H.M.S. *Basilisk*, Capt. Moresby, while cruising in Torres Straits and neighbourhood for the suppression of the Polynesian labour traffic, has added a valuable fact to the knowledge we possessed of the geography of New Guinea by the discovery of a new port and harbour in lat. 9° 30′ S., lon. 147° 10′ E., about 38 miles east of Redscar Bay, on the south-eastern coast. The discovery was made in February, when Captain Moresby, while searching for a river supposed to flow into the sea east of Redscar Bay, entered an inlet which proved to be the entrance to a magnificent harbour, with an outer and inner anchorage, to which the names of Port Moresby and Fairfax Harbour have been given. The natives are much lighter complexioned than those of the opposite coast, and are evidently of a much more friendly disposition.

A GREAT earthquake occurred at Valparaiso early on the morning of July 8. There were six shocks in succession. Many families took refuge in the streets, the damage to private houses as well as to the public buildings being considerable; and many deaths were reported. A statue lately erected to Lord Cochrane was wheeled half round on its pedestal. The earthquake was observed to come from the east, and was felt as far south as Curico.

THE *Telegraphic Journal* intends to offer to its students from time to time prizes for the best and most carefully considered paper on a given subject. The first of these students' prizes is one of 25*l.* to be awarded to the author of the best paper on "The Evidence of the Theory of Correlation of Physical Forces as applied to Electricity and Magnetism," received by the editor of the journal on or before January 1st, 1874. The funds for this prize have been kindly given by Mr. Edward Sabine, C.E. The prize paper will be printed in the columns of the *Telegraphic Journal*.

WE understand that 1,000*l.* has been generously presented to the Oldham School of Science and Art, by Mrs. Platt, widow of the late John Platt, M.P., who was its founder in 1865, and life-president. Since the opening, its artisan students have gained four Whitworth Scholarships of 100*l.* each for three years (two have been awarded this year); two Whitworth Fellowships of 25*l.* each; one Studentship at the Royal School of Mines; three gold, six silver, and five bronze Queen's Medals (the Medallists of 1873 are not yet announced). Twenty-four artisan students were examined by the Department last May, in Inorganic Chemistry—eighteen passed (nine first class, nine second class)—and twelve in Laboratory Practice. The Committee have granted funds to enlarge the Chemical Laboratory, also to establish one for practical work in Heat, Steam, Light, and Acoustics. Mr. J. T. Hibbert, M.P. for Oldham, has given a Local Scholarship of 25*l.* for the coming session. We have received a well-arranged time-table of Classes under the direction of Mr. Phythian, C.E., and Mr. Philip, M.A.

IN accordance with the resolution passed at the meeting, noted in last week's NATURE, for the promotion of technical education, at which H.R.H. the Prince of Wales presided, the Haberdasher's Company have sent to Lord Lawrence, for distribution by the London School Board, the sum of 20*l.* as their contribution towards the purchase of tickets of admission to the International Exhibition.

DURING the month of October, we learn from the *Journal of the Society of Arts*, notwithstanding the Anarchical State of Spain, an exhibition is to be held at Madrid, of national products and manufactures, of agriculture, mines, chemicals, industries, and graphic arts. Foreign products will be received by the executive at Madrid if carriage paid. Goods will be sold by the executive on a small commission charge. This is to be the first of a proposed series of Spanish exhibitions.

PROF. COPE sends us, as No. 14 of his "Palæontological Bulletins," the description of two new mammals from the tertiary "of the plains." One, *Aelurodon mustelinus*, is only known from some teeth of the molar series; the other, *Aceratherium megalodus*, is represented by a perfect cranium with

dentition of both jaws nearly complete, with other bones of other specimens. The wording of the description is intricate and short.

A PAPER entitled "A Study of North American Noctuidæ, by A. R. Grote, was read on July 2 before the Buffalo Society of Natural Sciences, declaring that six new genera (Ufeus, Ablepharon, Ommatostola, Argillophora, Harveya, Spiloloma) and twenty-seven hitherto undescribed species (Agrotis, 7; Ufeus, 2; Mamestia, 1; Dianthœcia, 1; Oncocnemis, 3; Hadena, 1; Ommatostola, 1; Cucullia, 1; Xylina, 1; Heliothis, 6; Argillophora, 1; Harveya, 1; Spiloloma, 1), occur in the N. American Insect Fauna.

SIR HENRY RAWLINSON's presidential address at the last anniversary meeting of the Geographical Society has been published in a separate form by Messrs. Clowes and Sons. We are glad to see it reproduced in a handy and well-printed form, for it contains a masterly summary of the progress of geographical knowledge during the past year.

WE have received the prospectus of what promises to be a handsome and valuable work, "The Fenland, Past and Present: its History, Geography, Geology, Natural History, Scenery, Antiquities, Climatology, Drainage, Agricultural Produce, and Sanitary Condition; illustrated with Wood Engravings, Maps, and Diagrams; by Samuel H. Miller, F.R.A.S., Fellow of the Meteorological Society; and Sydney B. J. Skertchley, F.G.S., H.M. Geological Survey." It will be published by Leach and Son, Wisbech; and Longmans, Green, and Co. London. Under the head "Fenland," the authors include that area of low, once marshy lands, in which the rivers Witham, Welland, Nene, and Ouse interlaced, including nearly 2,000 square miles, and roughly bounded by a line drawn from Lincoln by Bourn and Peterborough to Cambridge on the west; from Lincoln to Skegness on the north; from Cambridge and St. Ives to Brandon on the south; and from Brandon to Lynn on the east (thus including Boston, Sleaford, Spalding, Croyland, Thorney, Wisbech, March, Huntingdon, Ely, besides the border towns.)

A VERY deserving institution has recently been established in Cincinnati, under the title of the Cincinnati Acclimatisation Society, its object being to effect the introduction of such foreign birds as are worthy of note for their song or their services to the farmer or horticulturist. The society announces that during last spring it expended 5,000 dols. in introducing fifteen additional species of birds, and that it had already successfully accomplished the acclimatisation of the European sky-lark, which is stated to be now a prominent feature of the summer landscape in the vicinity of Cincinnati. Among the species which it is proposed to introduce is the European titmouse, considered abroad as one of the most successful foes of insects injurous to vegetation.

THE addditions to the Zoological Society's Gardens during the past week include a Harnessed Anntelope (*Tragelaphus scriptus*), a Double-crested Pigeon (*Lopholæmus antarticus*), two Senegal Touracous (*Corythaix persa*), two Chilian Tinamous (*Rhynchotus perdicarius*), a White-fronted Dove (*Leptoptila jamaicensis*), a Glossy Ibis (*Ibis falcinellus*), a Mauge's Dasyure (*Dasyurus maugæi*), a Barbary Ape (*Macacus inuus*), and others.

SCIENTIFIC SERIALS

Annalen der Chemie und Pharmacie Neue Riehe, Band xci. Heft 2 und 3, June 14. This number begins with communication No. 83 from the Griefswald Laboratory, the subject of which is Phenathren, by M. Hayduck. The author describes several of the compounds of this body.—From the same laboratory we have a notice on the compound $C_{14}H_8S_2$, by C. Pauly.—B. Rathke contributes a paper on the chloro-sulphides of carbon, and another on the compounds of the amides with that body. One of these chloro-sulphides has the formula $CSCl_4$—perchloromethylmercaptan, another the formula $CSCl_2$, several of their compounds are described. The same author also contributes a short paper on the changes nitro-compounds undergo in sulpho-acids.—Messrs. Maunder and Tollens communicate a paper on β Bibromopropionic acid, in which they give an exhaustive account of this body and its compounds.—Messrs. Caspary and Tollens have converted β Bibromopropionic acid into acrylic acid and give an account of the process, and of the salts of acrylic acid.—Mr. B. Tollens communicates a paper on the constitution of the allyl and acryl derivatives.—Prof. Max. von Pettenkofer has a paper on "Nourishment in general, and on flesh extract as an essential portion of human nutriment in particular."—Messrs. Lieben and Paterné have a paper on the dry distillation of calcic formate.—J. Wislicenus communicates a paper on the optically active lactic acid of flesh extract, and on paralactic acid. The same author also communicates some observations on ethyl-lactic acid. The next paper is by C. E. Groves on the formation of naphthaquinone by the direct oxidation of naphthalene, which has already appeared in the March number of the Chemical Society's Journal. Messrs. Hlasiwetz and Kachler, in a postscript to their paper on a new derivative of sulpho-carbaminic acid, mention the discovery of the body in question by Zeise in 1842. H. Ranke finishes the number with some experimental proofs of the possibility of the spontaneous combustion of hay.

Reale Instituto Lombardo di Scienze e Lettere Rendiconti, serie ii. vol. vi. Fascicoli x.—We notice papers on *Telobates fuscus*, by Prof. Emelio Cornalia; on the Italian earthquake of March 12, by A. Serpieri; on some geological theories, by G. Cantoni; on the inversion of currents in electromotors, by A. Ferrini. Besides these there are papers on Manzoni and on Kant's philosophy, the first by A. Buccellati, and the second by C. Cantoni. Fascicolo XI. contains only social papers, none of scientific interest. In Fascicolo XII., S. A. Lemoigne contributes a paper on the mechanism of rumination, and J. A. Serpieri one on the earthquake of March 12; S. A. Cantoni has a paper on the molecular movements of gases. The rest of the number is devoted to the section of moral and political science.

IN the *Annali de Chimica applicata alla Medicina* for June is a paper on the cremation of the dead, which practice is strongly advocated. The author, who is anonymous, states that in Belgium 7,500 hectares (1 hectare = 2·47 acres) are unproductive of food, through being used as cemeteries. He estimates the value of this land at from 38 to 40 millions (lire?).

SOCIETIES AND ACADEMIES

LONDON

Royal Horticultural Society, July 16.—Scientific Committee.—Dr. M. T. Masters, F.R.S., in the chair.—A letter was read from the locomotive superintendent of the Brighton Railway stating the results of the company's experience in using a mixture of chalk with coal for fuel. It was found that used for any other purpose than that of saving the fire-bars from Welsh coal (for which it is admirably suited) or for reducing the area of heating surface it increases the ordinary consumption of fuel considerably.—The Rev. M. J. Berkeley showed female flowers of *Lychnis diurna*, in which the calyx was reduced by arrest of development to a mere rim.

August 6.—General Meeting.—W. B. Kellock in the chair.—The Rev. M. J. Berkeley commented upon the fruits and vegetables exhibited. He mentioned the remarkable improvement in the quality of W. Indian pines owing to the introduction from England of the better cultivated kinds.—Prof. Thiselton Dyer pointed out that a curious cucurbit which had lately been introduced, rather as a curiosity than for any useful purpose, under the name of Sooly Qua, was a form of *Luffa ægyptiaca*, the common washing gourd. Another cucurbit known as the Toong Qua appeared to be identical with *Benincasa cerifera*.—A new method of propagating ipecacuanha had been devised in India by Mr. Jaffray, and promised to be of great importance. It simply consisted in striking the leaves upright in pots. These produced roots and the most superficial of these eventually produced buds.—As an interesting fact bearing upon the distribution of plants, an extract of a letter from Mr. Moseley, naturalist on board H.M.S. *Challenger*, was read. A vessel laden with grapes was wrecked on the coast of Bermuda a short time ago.

The boxes of grapes were washed ashore, and the seeds germinated in abundance, so that the governor was able to collect plants for his garden.

BERLIN

German Chemical Society, July 28.—O. Liebreich, vice-president, in the chair.—A. Laderburg described a simple way of obtaining zinc-methyl and its action on silicic ether. The result is a liquid boiling at 150° of the formula $SiCH_3(OC_2H_5)_3$, to which he gives the name ortho-silico-acetic ether. The same chemist, conjointly with Demole, has transformed chlorhydrine into acetochlorhydrine of glycol. The latter by treating oxide of ethylene with aniline has obtained a single base of the formula of phenylated mono-oxyethylene-amine $CH_2OHCH_2NHC_6H_5$.—O. Jacobsen has been able to investigate human bile obtained from a fistula of a strong and healthy man. It contained no taurocholic acid, while other human biles obtained from patients contained both glyocholic and taurocholic acids in variable proportions.—A. Faust has transformed monochlorinated phenol into resorcin (and not, as Peterssen communicated lately, into hydrochinon.—H. Limpricht has compared sulfo-ortho-tolindinic acid, and many of its derivatives, with those of sulfo-pseudo-toluidinic acid.—Thomas Dykes Barry described several derivatives of propiophenone $C_6H_5COC_2H_5$: viz., two isomeric mononitro-propiophenones, amido-propiophenone, and secondary propyl-benzol-alcohol $C_6H_5CH.OH.C_2H_5$.—G. Goldschmiedt, in treating benzol and bromal with sulphuric acid obtained diphenyl-tribrom-ethane $(C_6H_5)_2CH.CBr_3$. This treated with potash yields diphenyl-dibrom-ethylene $(C_6H_5)_2C_2Br_2$, and heated with zinc powder, it is transformed into stilbene $C_{14}H_{12}$.—P. Liechto has determined the atomic weight of molybdenum = 95·86, and describes the following chlorides:—$MoCl_2$, $MoCl_3$, $MoCl_4$, $MoCl_5$, and $MoO(OH)_2Cl_2$.—A. Michaelis and G. Köthe find that iodide of lead treated with sulphite of sodium yields sulphite of lead and iodide of sodium, and that the salt formerly described by Zinero $I_2SO_2(ONa)_2$ does not exist.—A. Michaelis and O. Schifferdecker describe the following compounds of sulphur:—SCl_4, existing only at temperatures below −20°, $S_2O_3Cl_4$, (a solid body obtained by treating SO_3HCl with SCl_4), and its product of decomposition by moist air $S_2O_5Cl_2$.—A. Mitscherlich described a new method of organic analysis. He replaced oxide of copper by that of mercury, weighs the reduced mercury, CO_2 and H_2O in the ordinary way and thus determines the oxygen contained in the substance, as well as the Cl, I, Br retained by the mercury or the sulphur and phosphorus transformed into sulphate and phosphate of mercury.—A. Borodin in treating valeric aldehyde with solid caustic potash at 0° obtained aldolic products of condensation of the following formula; $C_{10}H_{18}O$ $C_{20}H_{38}O_3$. The former left for three years with diluted soda yielded crystals of the composition

$$C_{20}H_{42}O_5 = (C_{10}H_{20}O_2) + H_2O.$$
(polymeric valeral)

C. Engles, by treating monochlorinated acetonitrile $NC.CH_2Cl$. with aniline replaced Cl by NHC_6H_5, thus obtaining a base, anilido-acetonitril.—A. Emmerling and C. Engles have obtained from acetophenone the corresponding pinacone and secondary alcohol.—E. Baumann, by treating cyanamide with sulphuric acid and water, has obtained a body of the composition of urea, but hygroscopic giving a nitrate of a different crystalline form, and a double salt with chloride of platinum, in fact differences that seem to indicate that this body is a new compound isomeric with urea.—E. Mulder described several derivations of uric acid and of urea.—C. Tiemann compared two methods for determining nitric acid in water. The wells of Berlin yield water containing terrific quantities of nitric acid, viz. 17 in 100,000 instead of 0·4 which is generally admitted to be the maximum quantity allowed for drinking purposes. It should be known, however, that the water-works supply the town with river water of good quality.—C. Biedermann showed beautifully coloured salts of mononitrophenol with alkalis and alkaline earths.—W. H. Pike, of London, has succeeded in obtaining some of the higher homologues of oxaluric acid by heating a molecular mixture of urea or sulpho-carbamide with an anhydride of a dibasic acid. The acids already obtained are succincarbaminic acid $NH_2—CO—NH—CO—C_2H_4—COOH$., succin-sulpho-carbaminic acid $OH_2—CS—NH—CO—C_2H_4—COOH$, and citracon-sulpho-carbaminic acid $NH_2—CS—NH—CO—C_3H_4—COOH$.—The next meeting of the society will take place the 13th of October.

PARIS

Academy of Sciences, Aug. 4.—M. Bertrand, president, in the chair.—The following papers were read:—A further portion of M. Hermites' paper on the exponential function.—A reply to M. Vicaire's theory of the sun, by M. Faye. The author controverted the statement that the sun is a cold mass of combustible matter burning at the surface only, in an atmosphere of oxygen.—On the determination of the wave-lengths of the lines in the ultra-violet, and also in the ultra-red parts of the spectrum by means of phosphorescence, by M. Ed. Becquerel.—On the action of armatures applied to compound magnets, by M. Jamin.—On the reciprocal displacements between the hydracids, by M. Berthelot. The author has been investigating the heat phenomena produced by these reactions.—Note on the cubic capacity and on the volume of air requisite to insure the healthfulness of inhabited places, by General Morin. The general gives the results of observations on barracks and hospitals. As regards the former, he thinks that 16—20 cubic metres of space are required per man, equal to 565—706 cubic feet.—The fourth part of M. A. Ledieu's paper on thermodynamics was then read.—An analysis of Dewalgnite from Salm Chateau, Belgium, by M. F. Pisani.—On the Cocuyos of Cuba, by Señor de dos Hermanas. The cocuyo is a luminous insect, said by M. Blanchard, at the conclusion of the paper, to belong to the genus *pyrophorous*, to which also a Mexican insect of the same name belongs.—Memoir on cerebral localisations, and on the functions of the brain by Dr. Fournie.—On polychromic photography, by M. L. Vidal. This was a description of a recently patented method of obtaining coloured prints by the use of various pigments, as in carbon printing.—M. Lichtenstein communicated a paper on the present state of the Phylloxera question, and M. Signoret one on the evolution of the Phylloxera.—Fourth note on the maximum resistance of magnetic coils, by M. T. du Moncel.—On electric condensation, by M. Neyreneuf.—Studies on nitrification, II., by M. Schlœsing.—On the corundum of North Carolina, Georgia, and Montana, by Mr. Laurence Smith.—On Roman essence of chamomile, by M. E. Demarçay.—On the characteristics of the true polyatomic alcohols, by M. Lorin.—On the variation in the amount of urea excreted under normal nourishment, and under the influence of tea and coffee, by M. E. Roux. The author found that these substances very largely increase the amount of both urea and chlorine voided in the urine, if they be taken after abstinence from them, but that when continuously used, the quantity gradually returns to its normal amount. Hence he regards this action as that of the washing out of accumulated urea.—On the uniformity of the action of the heart when that organ is free from external nervous influences, by M. Marey.—On some effects produced by lightning at Troyes, on July 26, 1873, by M. E. Parent.

PAMPHLETS RECEIVED

ENGLISH.—Improved Method of Recording Telegrams: Richard Herring.—Report of the Radcliffe Observer to the Board of Trustees, read at their meeting at Oxford.

FOREIGN.—Medizinische Jahrbucher heraus geben von der K. K. Gesellschaft der Arzte, redigirt von S. Stricker, Jahrgang 1873, Heft i. and ii. (W. Braunmuller, Wien.).—Ufversigt af Kongl. Vetenskaps Akademiens Förhandlingar, Trettionde Argangen, 1873, Nos. 2, 3, 4 (Stockholm).—Bulletins de la Société d'Anthropologie de Paris, Fasc. i, Jan. et Feb., 1873.

CONTENTS

THURSDAY, AUGUST 21, 1873

THE REPORT OF THE SCIENCE COMMISSION ON THE OLD UNIVERSITIES

I.

ONE of the two Royal Commissions appointed to inquire into University matters has just issued its Report, and it comes in the very nick of time; for while on the one hand the question of University reform is day by day attracting a larger share of public attention, on the other the Financial Commission may be expected to report shortly and make us acquainted with the actual resources available for fundamental reforms which all acknowledge must be made, though opinions differ as to the precise direction they should take.

When we state that the Report to which we refer has been drawn up by a Commission, the Chairman of which —the Duke of Devonshire—is the Chancellor of Cambridge University, and that to it are appended the names of Stokes, H. J. S. Smith, Sharpey, Huxley, Lubbock, the Marquis of Lansdowne, and Mr. B. Samuelson as Commissioners, the importance of the document becomes manifest. Nor is it lessened by the way in which the Report at its outset refers to "all those parts of human knowledge and culture which are not usually regarded as having any scientific character;" adding, "Least of all should we wish to imply that there is any antagonism between the literary and scientific branches of education and research; it is rather our conviction that neither branch can be neglected without grave detriment to the other; and that an University in which the Mathematician, the Experimental Philosopher, and the Biologist are actively engaged in the endeavour to advance human knowledge in their own provinces, is not on that account less likely to be productive of original labours in the fields of Literature and Learning."

The subjects are dealt with in the following order:—

I. The Courses of Study and the Examinations.
II. The Professoriate.
III. The Scientific Institutions within the Universities.
IV. The Colleges.
V. The Relation of the Universities to Technical Education, and to Education for Scientific Professions.
VI. The Duty of the Universities and the Colleges with regard to the Advancement of Science.

Under the first head an examination on leaving school equivalent to the German *abiturienten examen*, to be controlled by the Universities, is proposed, "so that the scientific student who had shown the requisite literary proficiency in the 'Leaving Examination' would find himself absolutely free, except so far as the examination in Divinity is concerned, from the first moment of his entrance to the University, to devote his whole time and energy to his scientific studies." The Commissioners adding their opinion that "any system which does not concede, from the first, this freedom to those students of Science who have given proofs of sufficient literary acquirements, involves an interference with their course of study which in many cases is prejudicial."

The opinion is also expressed that, in addition to the College Scholarships, University Scholarships in Natural Science should be founded at both Universities; scholarships comparable to those which already exist for various branches of classical learning, and, at Oxford, of Mathematical Science.

Under the heading of the Professoriate, lists of the Professorial and Collegiate teachers at Oxford and Cambridge are given and compared with similar lists for Berlin, with the remark that "it is impossible not to be impressed with the evidence which the list affords of the abundance and variety of the scientific teaching given in the University of Berlin by professors of great eminence. We would particularly call attention to the fact that the list includes not merely general courses adapted to the requirements of those students who are interested in Science only as a part of a liberal education, but also special courses on subjects taken from some of the newest and most interesting fields of scientific inquiry; so that instruction of the kind most likely to develop a scientific spirit in the mind of the learner, and given by the most competent teachers, is put within the reach of every student."

With regard to the proposed additions to the Scientific Professoriate, without attempting to decide what should be the ultimate organisation of the Scientific Faculty in Oxford, the Commissioners are of opinion that arrangements should be made at the earliest possible opportunity for the establishment of two Professorships in Physics, and two in Chemistry, in addition to those already existing; for the redistribution of the biological subjects (exclusive of those assigned to the Faculty of Medicine) in such a manner as to secure their being represented by five independent professors; and for the addition of two chairs, one in Pure Mathematics and one in Mathematical Physics. Lastly, they are disposed to recommend the establishment of a Chair of Applied Mechanics and Engineering.

Somewhat similar additions are proposed in regard to Cambridge.

So far we have dealt with professors of the first order, so to speak, but the appointment of adjoint professors, demonstrators, and assistants is also proposed in the following words:—

"Although the witnesses have been unanimous as to the necessity of strengthening the professorial staff, they do not entirely agree as to the way in which this should be done. Mr. Pattison would increase the number of independent Chairs of Science to twenty or even to thirty. On the other hand, there appears to be a feeling that the principal subjects should not be too much divided although it is admitted that at present they are too much grouped together.

"It must not be forgotten that an increase in the number of independent Chairs would render it necessary for the Universities to provide increased accommodation in laboratories, and additional apparatus. With the view of utilising to the utmost the existing appliances of this sort, some of the witnesses have suggested that the increase of the professoriate should, as far as possible, be provided for by an abundant supply of skilled assistants, of demonstrators, and of assistant professors, rather than by increased numbers of independent lecturers.

"The necessity for skilled assistants and for demon-

strators of course made itself felt at a very early period, and though a certain number of such assistants and demonstrators have been supplied, yet the need for an increase in the number of these subordinate offices has already become apparent. It may be mentioned, for example, that at neither University is any assistance of this kind at present afforded to the Chair of Geology, or to that of Botany.

"A Natural Science Professor should have, in the first place, sufficient skilled assistance to relieve him from all mere drudgery in the preparation of his lectures. In the second place, he should have such further assistance as may be necessary to enable him to carry on original researches. And, thirdly, although no professor would wish to hand over the superintendence of the practical teaching in his laboratories entirely to others, he should be enabled to discharge this duty of superintendence without an undue sacrifice of time. The work should be done under the professor's eye, but its details should be entrusted to competent demonstrators, appointed by and responsible to him.

"So far there is a general agreement; but the question whether assistant professors should be appointed at all, and if so, how far the dependence of the assistant professor upon the principal professor of the subject should be carried, has given rise to some divergence of opinion. We have already stated that we regard as indispensable the establishment of a certain number of new Chairs, to be independent of, and to take equal rank with, the existing Chairs. If the Universities are to become great schools of Science, it is of the first importance to secure for them the permanent services of a very considerable number of scientific men of established reputation; and we cannot perceive how this object is to be attained otherwise than by offering to such men, without any reservation whatever, the same academical *status* which has hitherto been enjoyed by the University Professors. We consider, therefore, that in any extension of the Professoriate, this is, without doubt, the first point to be attended to. But we are also disposed to attach great weight to the suggestion that, in addition to the Professorships representing the great divisions of Natural Science, University Teachers, who might be termed Adjoint Professors or Readers, should be appointed to undertake the instruction in special branches. It would be undesirable to place an Adjoint Professor in a position of complete subordination to the Principal Professor of the subject; and it would probably be very difficult to arrange any plan of partial subordination which could work satisfactorily. We are, therefore, of opinion that the Adjoint Professors should not be regarded as assistants to the Professors, but should be responsible for the due discharge of the duties assigned to them to a Board or Council, appointed by the University, and not to any individual Professor.

"It is important that the Universities should be able to secure the services of men who have shown their ability to promote Science, and to become successful teachers of it, by offering them places, such as the Adjoint Professorships, which would give them an opportunity of distinguishing themselves; and, with this view, it is very esirable that as much independence as possible should be allowed to the Adjoint Professors, in order to make the appointments attractive to the best men. On the other hand, as it is obvious that the perfection of the means and system of instruction in the Universities is of primary importance, an organisation of, and control over, the courses of instruction would be necessary, as otherwise there might be an excess of lectures in some subjects, and a deficiency in others. We are of opinion that these difficulties might be overcome, and a sufficient amount of liberty combined with systematic organisation, if, as we shall presently recommend, a Central Board, or Council, should be formed, representing the Scientific Faculty, and having definite functions with regard to the scientific teaching within the Universities.

"We may observe that the financial argument in favour of extending the Professoriate (at least in the first instance) by the institution of offices not intended to take equal rank with the existing Chairs, rather than by increasing the number of the Principal Professorships, will probably lose some of its force when a careful estimate is made of the difference which the adoption of the one plan or the other would make in the charge to be laid upon the funds of the Universities. It is quite true that the emoluments of an Adjoint Professor need not be so great as those of one of the Principal Professors; and that to this extent there would be a saving. But whether an additional professor of any subject be termed an Adjoint Professor, or whether his Chair be regarded as co-ordinate with the existing Chairs, the difficulty would always remain that if he is to be of any use at all he must be furnished with the necessary apparatus; he must have a room to lecture in, a room or rooms to work in, and the classification of the students will also probably require additional space. Laboratories of chemistry, physics, and physiology have been already provided; it would, therefore, not be necessary to create a large establishment for any new professor. But it is certain that the only way in which the Universities can increase the usefulness, at the same time that they increase the number, of the professors, is by being ready to make, from time to time, such moderate additions as may be necessary to the buildings which they appropriate to Science."

Under the heading "Duties of Professors," we have the following:—

"It has been suggested that, in the case of certain professorships at both Universities, the functions of Original Research might be separated from direct instruction. To a professor the duty of teaching is a matter of daily routine; whereas, original research is a duty which belongs to no day in particular, and which is, therefore, very likely to be neglected in comparison with the other. Nevertheless, we cannot see any just and sufficient reason, in the case of the professorships, for a total separation of the two functions; and even Sir Benjamin Brodie, who has supported the view that some distinction should be made between offices appropriated to teaching and those appropriated to original research, would not have the separation absolute, and would consider it of importance that even a professor whose chair was founded chiefly with the latter view, should be called upon to produce, from time to time, in the form of lectures, the results of investigations in new departments of Science. Lecturing is not the only mode in which scientific instruction may be imparted. A professor who should undertake the direc-

tion of a laboratory in which advanced students were to be trained in the methods of scientific research, would be very far from holding a sinecure office, and would be rendering the highest, as well as the most direct, service to scientific education.

"We have no doubt that for a professor the duty of teaching is indispensable, but we agree with the witnesses whom we have examined that original research is a no less important part of his functions. The object of an university is to promote and to maintain learning and science, and scientific teaching of the highest kind can only be successfully carried on by persons who are themselves engaged in original research. If once a teacher ceases to be a learner it is difficult for him to maintain any freshness of interest in the subject which he has to teach; and nothing is so likely to awaken the love of scientific inquiry in the mind of the student as the example of a teacher who shows his value for knowledge by making the advancement of it the principal business of his life.

"It has been, to a certain extent, a complaint against the School of Natural Science in Oxford that hitherto it has produced but very few original workers. The complaint (if well founded) may, perhaps, be accounted for by the circumstance that the school has not been long in existence; but there can be no question that it is of the utmost importance to impress upon teachers and learners alike that one, and perhaps the chief criterion of success in the teaching of Science is its leading to new discoveries. To promote this end the Universities probably can do nothing more useful than to increase the number of persons employed, under whatever name, in the teaching of Science, taking care at the same time that while such duties are assigned to them as may prevent their offices from being sinecures, they shall be left with time and energy enough to carry on original work. We consider this to be a point of great importance, and we should regret to see any scientific office whatever established in either of the Universities without its being understood that it is expected from the holder that he shall do what is within his power, not only for the diffusion, but also for the increase of scientific knowledge.

"It has been stated in some parts of the evidence which we have taken, that the duties of lecturing and teaching which are required from the professors are such as seriously to interfere with their leisure for original investigation, and a wish has therefore been expressed that the provisions of the Professorial Statutes as to the number of lectures to be given should be relaxed. We cannot concur with this suggestion. In estimating the amount of teaching and lecturing which can properly be required from a professor, we do not forget that he is expected to keep himself well acquainted with all the latest advances in some very wide department of knowledge, a task which, at the present rate of scientific productiveness, is no light one. But, on the other hand, we cannot leave out of sight that the University duties of a professor last for only six months, and that he has thus the invaluable privilege of being master of his own time for fully one half of the year. It is, therefore, only reasonable that during the University Terms he should devote a fair proportion of his time to the work of teaching. And we feel it to be our duty to say that, in recommending, as we have done, the foundation of a considerable number of new Scientific Professorships, our intention is that duties of a very substantial kind should be attached to each of these offices, with a view to the establishment of an efficient and complete course of instruction."

From the limited scope of the functions of the various existing administrative bodies, as well as from the constitution of one of them, the Commissioners consider that they cannot be regarded as representing, in any adequate manner, the Scientific Faculty of the University. They then add, "We are of opinion that the best mode of providing for this important object would be to replace them by a Single Administrative Body, representing every department of Science, and having wider but still definite powers entrusted to it. Without attaching any importance to the name, we shall, for the purposes of the present Report, designate this proposed administrative body as 'the University Council of Science.'

"The duties of the Council would, we conceive, be twofold—educational and financial."

(*To be continued.*)

HARMONIC ECHOES

According to Dr. Brewer * "The harmonic echo repeats in a different tone or key the direct sound. The harmonic is generally either the third, fifth, or tenth of the tonic. . . . On the river Nahe, near Bergen, and not far from Coblentz, is an echo thus described by Barthius:—It makes seventeen repetitions at unequal intervals. Sometimes the echo seems to approach the listener, sometimes to be retreating from him; sometimes it is very distinct, at others extremely feeble; at one time it is heard at the right, and the next at the left; now in unison with the direct sound, and presently a third, fifth, or tenth of the fundamental. Occasionally it seems to combine two or more voices in harmony, but more frequently it resembles the voice of a single mimic.

"At Paisley, in Scotland, there is a somewhat similar echo in the burying-place of Lord Paisley, Marquis of Abercorn. Musical notes rise softly, swell till the several echoes have reverberated the sound either in unison or harmony, and then die away in gentle cadence.

"At the Lake of Killarney, in Ireland, is a very celebrated harmonic echo, which renders an excellent *second* to any simple air played on a bugle. †

"There was formerly, according to the authority of Dr. Birch, an harmonic echo no less remarkable, seventeen miles above Glasgow, near a mansion called Rosneath. If a trumpeter played eight or ten notes, the echo would repeat them correctly a third lower. After a short silence another repetition was heard, still lower than the former; and after a similar pause the same notes were repeated a third time, in a lower key and feebler tone, but nevertheless, with the same undeviating fidelity. This echo no longer exists."

It is difficult to believe that these descriptions are accurate, but that they have a basis of truth there can be little doubt. My attention was first drawn to the subject

* "Brewer on Sound and its Phenomena." (1864.) P. 305.

† This must be a near connection of the equally celebrated Irish echo, which in reply to "How do you do?" answers, "Very well, thank you."—R. Or of that celebrated echo at Shoreditch Station, illustrated by poor Leech in *Punch*, where, to the old gentleman's call of "Porter," is replied "Don't you wish you may get him."—Ed.

by an echo at Bedgebury Park, the country residence of Mr. Beresford Hope. The sound of a woman's voice was returned from a plantation of firs, situated across a valley, with the pitch *raised an octave*. The phenomenon was unmistakeable, although the original sound required to be loud and rather high. With a man's voice we did not succeed in obtaining the effect.

At the time I had no idea that such an alteration of pitch had ever been observed, or was possible; but it soon occurred to me that the explanation was similar to that which I had given of the blue of the sky a year or two previously (Philos. Mag., Feb. 1871). Strange to say, at the very time of the observation I had in my portfolio a mathematical investigation* of the problem of the disturbance of the waves of sound by obstacles which are small in all their dimensions relatively to the length of the sound waves. In such a case (precisely as in the parallel problem for sight) it appears that the reflecting, or rather diverting, power of the obstacle varies inversely as the fourth power of the wave-length. When a composite note, such as that proceeding from the human throat, impinges on the obstacle, its components are diverted in very different proportions. A group of small obstacles will return the first harmonic, or octave, sixteen times more powerfully than the fundamental. After this, it is not hard to understand how a wood, which may be considered to be made up of a great number of obstacles, many of which, in two or three of their dimensions, are small in comparison with the wave-length, returns a sound which appears to be raised an octave.

The increased reflection is, of course, at the expense of the direct sound. If we conceive a group of small obstacles to act on a train of plane waves of sound, the effect will be a *diffused* echo, which may be heard on all sides, appearing to proceed from the group, and the direct waves which maintain their direction. If the original sound be composite, the diffused echo contains the higher elements in excessive proportion, and for the same reason the direct wave, being shorn of these higher elements, will appear duller than the original sound. It is well known that pure tones are liable to be estimated an octave too low, and thus it may be possible that a note in losing its harmonies may appear to fall an octave.

What is here called the direct sound may itself be converted into an echo by *regular* reflection. For example, if a plane wall were covered with small projections, there would be a diffused echo, due to the projections in which the higher elements preponderated, and an ordinary echo, obeying the law of reflection, in which the wave elements would preponderate.

I shall be much obliged if any one under whose observations echoes of this description may happen to fall, would communicate particulars of them to NATURE.

RAYLEIGH

LEITH-ADAMS' "FIELD AND FOREST RAMBLES"

Field and Forest Rambles. By A. Leith-Adams, F.R.S. (Henry S. King & Co.)

ONCE, on our expressing surprise to a friend at the fact of his having forsaken his usual line of study for another of a very different character, he remarked, "Well, you see it does not matter much what I take up, for whatever it may be, I am sure to make some discovery of value." The reply was sufficient to enable anyone to form an idea of the results that might be expected. He was an assiduous and earnest worker, but there was a certain deficiency in the quality of all he produced.

Mr. Leith-Adams is an assiduous and earnest worker; his opportunities in connection with his military avocations, have been considerable, and he has used them well. He has already given us the results of his experience in India and elsewhere in his "Wanderings of a Naturalist in India," as well as in the "Natural History and Archæology of the Nile Valley and Maltese Islands," and in the work before us he takes us to New Brunswick, vividly portraying the beauties of its short summers and, the discomforts of its dreary winters. An intense love for natural history has led him to make careful and prolonged observations as to the habits of most of the animals inhabiting the province of which he treats, together with the dates and direction of migration of the numerous migratory birds which are there met with. He has also paid considerable attention to the fish, and the geology of the district.

Our author, in endeavouring to obtain an accurate account of the past history of the native Indians of New Brunswick, found the task of more than ordinary difficulty, "inasmuch as, even apart from their persistent indifference to treat on any subject connected with their past history or present condition, there would seem to be an absolute incapacity to comprehend the meaning of such inquisitiveness on the part of the interrogator." Drink is the ruination of the remnant of this doomed race, a race so little advanced in the scale of humanity, that when it has disappeared, there will not be left a trace even of written or monumental record; "indeed, were it not for implements of the chase picked up occasionally, we should have few other data to establish the existence of the human inhabitants of the region, previous to the arrival of the first European travellers." The European colonist, as long as he is the possessor of the *mens sanus in corpore sano*, however, stands a better chance of surviving; nevertheless leprosy produces painful ravages among the original French settlers, on the north-east frontier of the province.

No explanation is attempted of the fact quoted from Dr. Gilpin, that many of the wild animals, as the bear, racoon, and beaver, which were driven from their haunts on the clearing of the forests, are again returning to the same districts, "to cultivated fields instead of primitive forests, to corn and maize, instead of wild fruits and berries." We cannot help thinking that this does not say much for the present assiduity of the farmers.

Albinism and Melanism, the tendency for certain individuals of a species to be white or black, is one of Mr. Adams' favourite subjects, and he gives it as his opinion that the reason why they in the wild state do not continue to propagate their peculiarity is because "the very decided difference as regards outward appearance would be sufficient to forbid intercourse between them and the typical individuals."

There is a want of point in many of the author's attempts at explanation of the various phenomena which

excite his curiosity. In considering the fact that the Cat-bird (*Mimus carolinensis*) has a strongly marked antipathy against the animal whose name it bears, he says, "I have often wondered if this inherited distrust of the cat could be explained in any way with reference to the imitative peculiarities of the bird. In other words, is it possible that some ancestor began to mew like a cat whenever it saw the wild cat in his haunts, and that in process of time it came to be an established habit?" Again, the answer given to the question, why such migratory birds as the ruby-throated Hummer (*Trochilus colubris*) are not content with the eternal summer of the south? is equally inconclusive: "All that we can say is that some inherited instinct is at work, perhaps to them as precious as is the longing for the holidays to the schoolboy, full of pleasant reminiscences, which of course would grow by experience." And we do not feel any nearer the truth as to the reason why the peculiarity of the beak of the Cross-bill is so well marked, when we know that in the bird's attempts to extract the seeds from the red spruce and other cones, "the bill, which is not so strong and conical as that of the pine bullfinch, became curved, until at length the condition became hereditary and transmissible."

An interesting remark is made, which illustrates how very susceptible the animal body is to the influence of slowly-acting external circumstances. For it is the popular belief in New Brunswick that the severity of an ensuing winter may be predicted by the amount of fat present on the intestines and omenta of animals, whether wild or domesticated; and as the coldness of the winter must depend on the previous climatic condition, that may reasonably be supposed to affect the constitution in a manner favourable to the individual.

In conclusion, we think that both sportsmen and naturalists will find this work replete with anecdote and carefully recorded observation, which will entertain them; at the same time they will not put down the book without feeling that they have acquired much new information on the physical geography and natural history of New Brunswick.

HOEFER'S "HISTORY OF PHYSICS AND CHEMISTRY"

Histoire de la Physique et de la Chimie. Par Ferdinand Hoefer. (Paris: Hachette, 1872.)

MORE than twenty years ago M. Hoefer published a History of Chemistry, the first which had appeared since the publication of Dr. Thomas Thomson's History. M. Hoefer has since been known to us as the author of the biographies of various scientific men in the *Nouvelle Biographie Générale*, and of a small work entitled *La chimie enseignée par la biographie de ses Fondateurs.* The volume before us is one of a series which treats of universal history, and is published under the direction of M. V. Duruy. The works which it comprises are intended to be used in colleges and schools, and M. Hoefer's volume has no doubt been included, because the promoters of the series have wisely considered that the history of matter, and of motion, are as worthy the attention of the rising generation as the history of languages numbers, peoples, faiths.

Out of the 553 pages which the work contains, no less than 314 are devoted to the history of Physics, while the remainder contain in a condensed form the substance of M. Hoefer's larger *Histoire de la Chimie.* The History of Physics is divided into two books, entitled respectively "Matter" and "Motion," the former including—1. The immediate properties of matter (weight, volume, density, elasticity, compressibility); 2. The terrestrial atmosphere; 3. Liquefaction and solidification of gases; 4. Hygrometry; 5. Acoustics.

The second book on Motion includes—1. Gravity; 2. Heat; 3. Light; 4 Electricity and Magnetism.

We feel bound to take exception to this arrangement, which is both immature and ill-considered. For why has M. Hoefer classed *weight* with *matter*, and *gravity* with *motion?* and why *liquefaction and solidification of gases* with *matter*, when they are operations distinctly connected with motion? But, worse than all, why has he classed *acoustics* with *matter?* Again, he has omitted all mention of certain sciences which were among the earliest—Statics, Dynamics, Hydrostatics, Hydrodynamics. These sciences, from their antiquity, lend themselves with great facility to the apt illustration of the various phases of the history of science. Archimedes has received an altogether insufficient amount of notice: we may not forget that several of our sciences actually owe their origin to him; and how M. Hoefer, with Peynard's fine edition of the works of Archimedes in his own language, can have overlooked him, we are quite at a loss to understand Then the Archimedian screw, the pumps of Ctesibius, the Δυναμεις of Hero of Alexandria, should all have full mention in the work. And if it be urged that space did not permit mention of these things, we would reply that they are of far more importance than Hygrometry, which finds mention in the book. Also such sections as "Pèse-liqueur d'Hypatie," "Manomètre," "Hygromètre condenseur," "Porte-voix," "Clavecin et carillon electrique," "La beatification de Bose," might all have been replaced with advantage by more important matters.

We notice with regret a tendency to attribute discoveries to men who were not first in the field. Thus, although Boyle discovered his law of the compression of gases, no less than *fourteen years* before Mariotte, it is called *Loi de Mariotte.* Again, M. Hoefer says, "Gassendi paraît s'être le premier occupé de la question de la vitesse du son, sans préciser les résultats auxquels il était parvenu." But if M. Hoefer will read Lord Bacon's *Historia Soni et Auditus*, he will find a good deal of valuable and suggestive matter, among other things, a suggestion for determining the velocity of sound.

Let us turn to the comprehensive little treatise on the history of chemistry, beginning with Hermes Trismegistus, nay, with Moses, and ending with Wurtz, Williamson, Frankland, and Kolbe. This part of the work, as derived from M. Hoefer's larger treatise, is altogether more matured than the preceding; yet it is not without evidence of hasty selection and ill-considered statements. We cannot agree with M. Hoefer when he tells us that the word chemistry was used in the fourth century, and that we are to trace it to χυΐκὸν and χύω. Neither, for various reasons, which we have stated elsewhere, can we

accept the Greek MSS. attributed to Zozimus, Pelagius, Olympiodorus, Democritus, Mary the Jewess, and Synesius, as exact evidences of date or knowledge. In regard to more modern matters we regret to find no account of Robert Hooke's important theory of combustion. We are glad to observe that M. Hoefer does not echo the Wurtzian aphorism: "La chimie est une science Française, elle fut instituée par Lavoisier d'immortelle memoire." More liberally our author says, "Tout en suivant chacun une route différente, trois chimistes ont fondé, vers la fin du dix-huitième siècle, la chimie moderne: Priestley, Scheele, et Lavoisier, un Anglais, un Suédois, et un Français."

We should be glad to see in our own country the history of matter and of motion studied side by side with the history of languages and of numbers. Prof. Kopp lectures on the History of Chemistry in the University of Heidelberg, and no doubt his example is followed in other of the German universities. M. Hoefer's work is in many ways suitable for use as a text-book; it is cheap, it is anything but dull, and whatever the errors of arrangement may be, it contains a great deal of information.

G. F. RODWELL

OUR BOOK SHELF

An Essay on the Physiology of the Eye. By S. H. Salom. (Published by the Author.)

THAT the study of formal logic is not in itself conducive to sound reasoning will be acknowledged by many, but it is seldom that the truth of the statement is so fully illustrated as in the short work before us. The author has studied the writings of Hamilton, Mill, Bain, and others, and with a creditable enthusiasm endeavours to employ the new powers he thinks he has thereby acquired, in developing a hypothesis of his own to account for the phenomenon of vision more satisfactorily than those already accepted. An outline of the arrangement, which is partly disguised at first sight by the many technicalities and circumlocutions employed, will be almost, if not quite, sufficient for most of our readers. Commencing with a notion broached by Erasmus Darwin, that visual perception ensues from retinal motion derived through the motile force of light, the author hopes, "by turning the light of modern histological discovery on Darwin's theory of involuntary animal action, to succeed in convincing associational psychologists that this theory must henceforth be included in the creed of *à posteriori* thinkers." With this as a basis, the doctrine promulgated may be thus summarised. The eyeball being in a constant state of reflex action on account of the light acting dynamically on the retina, the motion thus produced exerts in the muscles surrounding the eye feelings of muscularity similar to those excited when we voluntarily determine ocular direction, and consequently without any voluntary effort, we are constantly aware of visual space properties. To prove this novel hypothesis the structure of the retina has to be fully entered into, and in a most ingenious manner solid fact is distorted to satisfy unsubstantial theory. Taking a single example of the reasoning employed, we find that it is necessary for the theory that the fovea centralis of the retina should be elastic; that it is so is evident from the following considerations:—"In the copious index of that exhaustive anatomical work, 'Quain's Anatomy,' under the heading 'yellow,' we find, in addition to 'yellow spot,' four substances *only*, namely—

Yellow cartilage,
" fibres of areolar tissue,
" ligaments of the vertebræ,
" tissue.

And on referring to the pages of the book in which these subjects are treated, we discover that *they have the common property of being elastic.*" From this on one of Newton's rules for philosophising "we are bound to frame the following physiological induction,—*all yellow anatomical substance is elastic*" We can hardly think that the author is not attempting to fool us.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

Atoms and Ether

ATTEMPTS to dispense, in physics, with the ideas of direct attraction and repulsion, however interesting, lead generally to a *petitio principii*, and I fear Prof. Challis's view, to which attention is called in NATURE of August 7, cannot be received as an exception.

For an ether of which the density can be varied is a substance that can be compressed and expanded, and what idea is in our minds when we speak of compression and expansion in a really continuous substance? Continuity implies space, and space that is full. Can space be more than full? When we say that a fluid is compressible and elastic, do we mean anything else than that it is made of parts which can be pushed closer together, and which, being so pushed, will push each other back? But this is repulsion and action at a distance. We do not alter the fact by calling the substance ether, and relieving it from the influence of gravitation.

Is a continuous substance, which is capable of compression, conceivable? I think not; or if it is, the conception is at once more difficult and more opposed to sensible experience than that of attraction and repulsion.

The substance of a bar of iron is not continuous. If I draw one end of it towards me, why does the other end follow? What can be the relation between the movement of my end of the bar and the ethereal vibrations which must propel the other end and all intermediate parts in the same direction?

Liverpool, Aug. 9 ALBERT J. MOTT

Instinct

Sense of Direction

THE perusal of the correspondence published in the February and March numbers of NATURE now to hand, and also your article on "Perception and Instinct in the Lower Animals," in the number of March 20, has induced a belief in my mind, that I may perhaps be able to contribute some evidence bearing upon the question at issue; and also that it may have some value from having been obtained from a field of observation not generally accessible, and from the fact that cattle and horses in Australia are subject to very different conditions to those obtaining in England.

I may commence by stating that the question, whether animals have or have not a peculiar power of finding their way from place to place, suggested itself to my mind very shortly after I first went into the Australian bush, now more than twenty years ago. It was not long before I satisfied myself that in many horses this faculty was strongly developed, but yet unequally in different individuals. I afterwards ascertained that it also existed in cattle.

Not only did I find that horses had extensive memories for places, being enabled to recollect a track they had followed some time previously, but also to remember the way from one place to another where no track existed. I found that not only had horses this exact memory, but that they possessed another gift which at first appeared to me inexplicable. This was, that when ridden through the bush, many horses would never, for a moment, as it were, lose the recollection of home, but "bear away" in its direction. I remarked this not only in a district with which the horse might be acquainted from grazing in it, but also when travelling and absent for the day from my camp, and from the other horse or horses, the "mates" of the one I rode.

Further than this, I also found that as regarded myself, I never lost the distinct perception of the direction in which my home, or camp, or starting-point for the day was situated, and in endeavouring to trace out and analyse this feeling, I at last came to the clear perception that it depended upon an unconscious action of the memory thus recording the alterations of the courses I had followed, and which by an effort of the memory I could recall. On this point I feel quite clear, for from the practice of paying especial attention during constant explorations to the course travelled, both for the purpose of keeping a correct dead reckoning, as also for the delineation of the features of the country passed over, I have found the faculty intensified, and the process more evident to myself. I may say that during the course of those twenty years' experience, I have never found the faculty at fault.

I believe in this lies the explanation of the power possessed by cattle and horses of finding their way from one place to the other irrespective of the road they may have gone.

I now propose to record some instances showing how cattle and horses in this district have endeavoured to reach the places where they were reared, and the truth of which I do not in the least question. To show how frequently such cases are met with here, where horses and cattle are bred in a half wild state at large in the bush, I may note that on determining to make this communication, I spoke to the first persons I met with who were likely from their pursuits to have noticed instances of the nature I required; of these persons, four at once gave me the particulars I am about to relate. But before doing so I must further remark, as bearing perhaps not remotely upon the question, that I have not met with aboriginal natives, either as savages or as "tame blacks," who possessed any power of finding their way from place to place differing in its nature, though perhaps in its degree, from that to be found in every good "bushman" among the whites. Their knowledge of country is entirely local—special as regards the district belonging to their tribe or family—general as regards the country of the neighbouring tribes. They know it thoroughly because they have been born in it and have roamed over it ever since. Out of their own locality I have found them to be inferior to a good white "bushman," in so far that they are unable to reason out any problem relating to the features of the country, and my experience has shown that out of their local knowledge I could never rely upon one of them in preference to my own judgment. I have remarked also that very few could, even in their own districts, travel straight from one place to another, say at twenty miles' distance. I now refer especially to the aborigines of that part of the interior of the continent lying on each side, north and south, of Sturt's Desert and including Cooper's Creek. As a rule they would "give and take" some 30° on each side of the course, correcting the direction from time to time as they recognised the "lay of the country" from rising ground.

In order that the instances I shall now quote may be more clear, it will be necessary to say in the first place that all the localities mentioned below will be found named in the maps published by the Surveyor-General of Victoria, and no doubt also in others. The only exception is Deadcock Creek, which is however shown as a small stream falling into the Mitchell River, on the west side below Cobbannah Creek. All cattle and horses brought down from the Maneroo table-land in New South Wales to the Gippsland market, travel by one road *vià* the Black Mountain, Buchan, Bruthen, Bairusdale, and Stratford; the distance from the centre of Maneroo district, say where the 149th meridian crosses the Snowy River, to Stratford, is about 180 travelled miles, and the number of cattle brought down annually may be about 12,000; of these a certain percentage escape and make their way back to the place where they were bred unless recovered on the way or hindered by natural obstacles. There is no other way from Maneroo into Gippsland excepting the one mentioned, and the country northward between that road and the Great Dividing Range is occupied by high and rugged mountains, dense forests, and thick scrubs. The road from Maneroo crosses the rivers flowing from the Great Dividing Range.

1. About four months ago a mob of cattle was brought down from O'Rourke's Station, the Black Mountain, Snowy River, and sold at Stratford. After being two months on the Bushy Park run near Stratford, fourteen bullocks escaped from the paddocks, and on search being made were recovered at the junction of Deadcock Creek with the Mitchell River. The line they had taken if carried out would go near the Black Mountain.

2. A horse bred by Mr. Sheen of Omeo was taken down *via* Bruthen, Bairusdale, and Stratford, and sold; was broken into harness, and worked by Mr. McFarlane, a contractor; was lost near Stratford, and on search being made was found at the junction of the Wentworth and Mitchell rivers. The line taken in this case is direct for Omeo.

3. Mr. Dougald McMillan of Stratford some little time back bought a mare from a Maneroo "mob." About a month ago she was lost from near Stratford in hobbles and was seen a day or two afterwards crossing "Iguana Creek still in hobbles and as fast as she could go." The people from the Glenalladale Station (Iguana Creek) being then engaged gathering some wild horses at Deadcock Creek, found her with them. This line taken was the usual one, and if carried out would cross the centre of Maneroo.

These three cases were related to me by the stock-keeper at Glenalladale Station.

4. A year or two back Mr. Kreymborg of Bairusdale purchased a mob of horses from O'Rourke Station, Black Mountain, and sold one, a black mare, broken to lead to a person named Gee, living at Cobbannah Creek. The mare remained with Gee's horses for some time, but was then missed from Lower Cobbannah Creek and next heard of at Tabberahberah, and was recovered on Pettersen's Station, at the foot of Mount Baldhead.

This line bears a little away from the Black Mountain, but the nature of the country is such that the Mount Baldhead and Notch Hill tier of mountains form the end of a *cul de sac*, of which the open country at the junction of the Wentworth and Mitchell rivers is the mouth. This tract of forest country fenced in by mountains a few years ago swarmed with stray cattle and their progeny; three hundred bulls were shot by the then proprietors in, I believe, about two years.

5. Mr. Freitag, who follows the occupation of packing up goods to the Crooked River gold-workings, tells me that he is in the habit of buying Maneroo horses at Stratford and breaking them in for use in his pack-train. He finds that for the first few trips they require watching carefully when camped at Iguana Creek, where the road to Crooked River turns northward, as they are very apt to make away at that place. When recovered they are usually found either at Deadcock Creek or up the river towards Tabberabberah, thus conforming strictly to the direction taken by cattle and horses in other instances.

6. Thomas Dowling, employed in the stations of Messrs. Degraves, at Omeo, bought a mare from Mr. McKeachie, of Delegete in Maneroo. The mare was kept in the Hinnomungie paddock (Omeo) for two or three years. Being then taken to Bindi, about twelve miles distant, she escaped, and after being seen at Nannyong, was recovered at Gelantipy, on the Snowy River. Nannyong is a small open piece of country on the summit of the mountain east of Bindi, and the country crossed over, fifty miles, is very difficult, the mountains being some 4,000 to 5,000 ft. in altitude, and almost unknown even now except to stock-men. I came through, last summer, nearly in the line the mare must have taken. It is almost direct for Delegete.

7. A bullock-driver named Richardson purchased a working bullock which had been sent down from Maneroo by the usual road for sale. He sold the bullock at Omeo—going up there with loading—to Mr. Lewis, the manager of Messrs. Degraves' stations. The bullock was kept in the Hinnomungie paddock, but got out two or three times, and in each case made away across country direct for Maneroo, being recovered by the Messrs. Pendergast, of Mt. Leinster, and sent back to Mr. Lewis.

These cases I have obtained from Mr. Lewis, and they are remarkable as showing the length of time during which cattle and horses retain the recollection of their native places, and also as showing, in even a more marked manner than those quoted first, that they return homewards without any regard to the track by which they have reached their place of departure. The cases from Stratford, on the other hand, illustrate the distances from which cattle will start for home.

8. Mr. Mackintosh, of Dargo, informs me that about two years ago, when gathering wild cattle on the Avon River, he got away from his men down that river for many miles before he ascertained that he was astray. Finding, then, that his horse persisted in going in a certain direction, he gave him his head, and the horse went in a straight line to the place where the camp was fixed, a distance of some ten miles through a scrubby country, and without a track.

I could continue quoting examples still further, but I fear that

I have already trespassed too much on the columns of NATURE, and I shall conclude by saying that these instances are not thought extraordinary here, and that the belief that cattle and horses can find their way "straight" is firmly held by all bushmen. I have heard similar instances at Lake Torrens, the Darling River, and Maneroo.

I am aware that they do not affect the question as to how a cat finds her way home when conveyed shut up in a bag, but I conceive that they bear out the view suggested by Mr. Darwin, and with which my own experience coincides.

A. W. HOWITT

Bairusdale, Gippsland, Victoria, May 21

Ingenuity in a Pigeon

THE following facts (having been witnessed by myself) may, perhaps, be considered worthy of insertion in your journal, as bearing on the subject of "Perception and Instinct in the Lower Animals," which has lately been brought into such prominent notice.

On the Richmond road (Surrey), at about a mile from the town, stands an old roadside inn, yclept "The Black Horse," owned by one R. Ketley. Attached to the house are a number of domestic pigeons of various breeds, chiefly "Pouters."

Having occasion to wait for my pony to be harnessed at this inn a few years since, my attention was directed by a gentleman (a resident of the neighbourhood) with whom I was acquainted, to the strange conduct of one of these birds.

A number of them were feeding on a few oats that had been accidentally let fall while fixing the nose-bag on a horse standing at bait. Having finished all the grain at hand, a large "Pouter" rose, and flapping its wings furiously, flew directly at the horse's eyes, causing that animal to toss his head, and in doing so, of course shake out more corn. I saw this several times repeated; in fact, whenever the supply on hand had been exhausted.

I leave it to your readers to consider the train of thought that must have passed through the pigeon's brain before it adopted the clever method above narrated, of stealing the horse's provender.

Was not this, indeed, something more than mere instinct?

RICHARD H. NAPIER

Upton Cottage, Bursledon, Southampton, Aug. 13

The Origin of Nerve Force

I NOTICE in NATURE for July 21 a paper by A. H. Garrod, suggesting that nervous force has its origin in thermo-electric currents due to the difference of temperature between the surface and interior of the body. Without presuming to any opinion from the physiological point of view, I venture to mention one or two obvious difficulties.

Although, as the writer observes, "in cold weather the impulse to act is much more powerfully felt than in summer, when the air is hot, and therefore the temperature of the surface is higher," yet even 98° F. (the internal temperature of a healthy body) is not uncommon for the air in tropical climates, where the natives can undergo great exertions. But, according to the thermo-electric hypothesis, the nerve force must in this case be *nil*. Again, temperatures of 140° to 160° F. are easily sustained for a considerable time in the Turkish Bath. Under these conditions the direction of the current should be reversed; and, even supposing that positive and negative currents both acted in the same sense on the muscles and nervous ganglia, it would seem that there must be an instant of transition when the two should be balanced, and nervous force at zero, and the powers both of sensation and motion lost with it.

The thermo electric theory is not required to explain the cases to which Mr. Garrod alludes. We have only to consider that the body must be kept at a constant temperature of about 98° F., while heat is being continually evolved internally by nervous and muscular action, to see that the surface of the body must be cooler than the interior in order to get rid of the superfluous heat without consumption of work in increased perspiration and evaporation. At high external temperatures there will naturally be disinclination to muscular exertion; not only because it produces heat which tends to upset the equilibrium of temperature, but because the force that would have been expended in it is consumed in increased action to get rid of the heat. That the exhausting effect of hot water is much greater than that of hot air is accounted for both by its greater conductivity and specific heat, and still more because it checks evaporation, which is one of the most powerful outlets for waste heat. It must be familiar to everyone that rapid exhaustion is produced by immersion not only in hot water but in that of almost any temperature. Taking 70° as an average external temperature, we shall find that immersion in water at 30° would be quite as rapidly destructive of nervous energy as in that of 110°; and that while air of the latter temperature could be sustained by the naked body for long without inconvenience, that of 30° would be rapidly fatal unless the temperature was kept up by violent exercise.

Supposing the brain to be really colder than the blood, I shall be glad if some physiologist will inform me if this is not due to the consumption of heat in building up the complicated and unstable matter of the brain from the comparatively stable and simple constituents of the blood, and in this case, if there is any difference of brain temperature between times of rest and nutrition (sleep) and those of active exertion.

Knowing as we do that chemical action is constantly going on in the body and that electrical disturbance is an almost constant result of such action, it seems hardly necessary to look further for the *source* of nerve force, though we are in almost complete ignorance of the details of its production.

HENRY R. PROCTER

The Flight of Birds

YOUR correspondent, J. Guthrie (vol. viii. p. 86), has struck a note which will, I think, echo. The question he raises is one which has exercised more minds than one. It has been present to me individually almost ever since I was able to reason. The opportunities enjoyed by exiles, especially in tropical countries, for the study of the phenomenon of a body, poised in mid-air, with no apparent support, is considerable, owing to the boldness and number of kites and birds of that class. I have watched them from the point of view—figuratively speaking—of your Cape correspondent, scores of times, and sometimes under peculiar conditions: but I am unable to add anything *certain* to the bare statement that birds of prey *can* maintain a position of absolute apparent rest.

It is some fourteen or fifteen years since I first watched an eagle in a telescope, with a view to test an explanation—the same as that suggested by Mr. Guthrie—hazarded as a conceivable possibility by my father, long before. Since that day I have had innumerable opportunities for close watch—some of which I will describe—and never have I seen anything to support it.

Not to go back too far, as I must trust to memory, I was, two or three years ago, on the summit of a long-backed solitary hill, 500 or 600 ft. high, in the Coimbatore plains of Southern India. There was a light breeze blowing, and I saw an eagle stemming it, on the leeward side of the hill, which was steep. Sometimes he was within (say) fifty yards, and having a good glass at hand, I rested it on a stone heap, and watched him. It was frequently possible to see him thus, stationary in a motionless field of view, at an apparent distance of 10 or 12 ft. Not a feather quivered: the head was turned from side to side as he scrutinised the hill-side: occasionally a foot was brought up to the beak: the roll of the eye was perceptible: but otherwise he was *at rest* to all appearance. Of course the tips of the wings came in for a share of my scrutiny. They may have been quivering, but they looked as steady as those of a stuffed specimen. And here I may observe, that for this appearance to be compatible with an unperceived vibration, the position of rest must have existed alternately with successive excursions, and the time occupied by the latter must have been insignificant as compared with the duration of rest. I find it impossible to accept this explanation, even as a first step, and need not inquire how it would produce the supporting effects. The tail, I should mention, was not at rest. It was frequently feeling, as it were, the passing breeze.

It is to be understood that in the course of frequent changes of general position, I had the bird under examination from different directions—not always of course so favourably.

On another occasion I spent a fortnight on the summit of a peculiar hill in this neighbourhood, with nothing to do but recruit as fast as possible. The hill resembles a dish-cover at top, and being the resort of fugitives from the dust and drought and heat of Bangalore in April and May, who occupy every available dwelling on a very restricted space, there is plenty to attract the kites from far and wide, to say nothing of vultures. There are two or three kinds of kite, but for the present subject they are all the same—fine, powerful, bold birds, with a stretch of

three or four feet of wing—who will swoop and take meat from a basket on a man's head, any day, or even from his hand. A score or two of these circling about the kitchen and outhouses, may be watched with advantage from the house-top, as is evident. The difficulty is to reproduce, in description, anything definite, from the copiousness of the evidence. I can therefore only express distinctly the conclusions I formed :—(1) that it was utterly incomprehensible ; (2) that there *must* be some unperceived source of motion ; (3) that it *might* be (and probably was), a subtle utilisation of the varying air currents met with or sought for. This conclusion lands one in a new set of perplexities, it is true ; but it is the least opposed to reason, however ill it may accord with some of the facts as interpreted by us.

Vultures are large heavy brutes, with comparatively little wing-power, and their flight is far slower and heavier. They very commonly rest on the ground, doing nothing, and if disturbed, the effort to rise is evidently a toilsome one. Nevertheless, they too possess, and largely exercise the power, of sustaining themselves in mid-air without apparent *action*. Not that they ever rest motionless, but they sweep about in endless paths with hardly ever a beat of the wing except on occasion, in this respect seeming to husband their strength much more than the kites, who are always on the move, and wheel in much sharper curves.

I was a good deal impressed, at one time, with the notion that the secret lay in slants of wind taken advantage of, but the more I see the less I like it. It is impossible to conceive upward currents as commonly strong enough to support a *dead* bird similarly extended. And though I am not prepared to assert that I have ever seen birds floating motionless where there was *no* wind, yet if we are to take the vertically resolved portion of wind, considered as essential, as the supporting agency, what becomes of the horizontal force? Given a sufficient momentum, one could conceive an economic expenditure of it, but not enough to explain the endless wheelings of vultures, much less the long continued poising without forward or backward movement of eagles.

In fine, I can only echo Mr. Guthrie's appeal for further explanation ; but I beg that we may have no nonsense about "bones filled with air." One is tempted to ask in that case if death *solidifies the bones*, to account for the undeniable weight and density of a goose. J. HERSCHEL

Bangalore, July 6

Earthquakes in the Samoan Islands, South Pacific

ON two former occasions I have contributed to NATURE notices of the earthquakes experienced in these islands. I will now continue my list from the commencement of 1872.

On March 22, at 1.25 P.M., there was a shock from N.E., motion horizontal. Vibration continued 15 seconds. For several seconds before the motion was felt, and during the whole time of vibration, there was a noise like distant thunder.

On April 8, at 3.10 P.M., there was a slight shock, horizontal.

May 11, at 10.20 A.M., we had a double shock. This was rather severe. Motion horizontal ; interval between shocks, 15 seconds ; total duration, 25 seconds.

May 28, at 10.30 P.M., a slight horizontal shock.

Sept. 9, at 10.20 P.M., double, horizontal shock from N.E. ; interval 25 seconds. This was a more severe shock than we usually feel here.

Nov. 12, at 5.10 A.M., a slight horizontal shock.

Dec. 3, at 9.20 P.M., a slight horizontal shock.

Jan. 2, 1873, at 7.40 A.M., a shock which, in these islands, is considered very severe. The motion was horizontal. The main undulation was followed by rapid oscillations for 45 seconds, followed by a sea-wave.

I regret that I cannot give full and definite information respecting this earthquake. I was away from home at the time, staying at the inland residence of the British Consul, on the island of Upolu, where I was unable to note with precision any of the accompanying phenomena. The Consul's residence is a wooden building with a ground floor only. It stands due east and west. This shook very severely with the rapid undulations of the earth-waves, apparently, longitudinally from east to west. I at once thought the centre of impulse was to the east of my position. Of this, however, I am by no means certain ; in fact, I have reason to doubt whether my observation on this point was correct. The sea-wave was almost entirely confined to the south coast of the islands of Upolu and Saraii. On the island of Tutuila (forty miles to the east of Upolu) it rose equally on the south and north sides. I have at present no information from Manua (three islands about sixty miles east of Tutuila) except that both earthquake and sea-wave were felt there. None of those who saw the sea-wave noticed particularly the time which elapsed between the earthquake and the rolling inland of the sea-wave. All my informants from Sarail (the most westerly island) agree that the one followed the other almost immediately. They felt the earthquake and almost immediately afterwards saw the reef bare much lower than it is at low tide. The tide was at about half-ebb at the time. Following closely on this efflux came the reflux in a large wave which rolled inland and flooded the sites of villages lying low at the back of deep bays. This wave rose about 6 ft. above high-water mark during spring tides. The rise and fall during spring tides in this group being about 4 ft. 6 in. The first great wave was followed by a number of smaller waves, and the oscillation continued for some time. No efflux of the sea was noticed, as far as I can learn, on Upolu or Tutuila. At the latter island the sea-wave rolled inland more than half-an-hour after the earthquake, and rose about 6 ft. above high-water mark. No damage of importance was done by the wave.

Two days after the above earthquakes, we had three others in rapid succession, and three more have followed them on different days since, viz. :—

On Jan. 4, at 10.45 A.M., we had a heavy horizontal shock, or rather a succession of shocks, two of which were severe. These continued 55 seconds, and were accompanied by great rumbling and a hissing noise.

Four minutes afterwards, viz., at 10.50 A.M., we experienced another sharp shock, accompanied by similar noises. The vibrations of this shock continued 15 seconds. We had scarcely recovered our equilibrium and quieted our nerves after this second shock when, at 10.57 A.M., we were startled by another, the oscillations of which lasted 20 seconds. This also was accompanied by great rumbling.

No damage was done by these earthquakes. The buildings in these islands are all low, and nearly all are built with wood, so that only a very severe earthquake could do much injury.

On Jan. 8–9, at midnight, another slight horizontal shock was felt.

On Jan. 13, at 8.45 A.M., we had another which was also slight.

On Jan. 14, at 5.24 A.M., there was another slight horizontal shock.

The Samoan Islands owe their existence to volcanoes, as they consist almost entirely of volcanic rock. There has, however, been no eruption for a very long period until in 1867, when, it will be remembered, a submarine volcano burst out between Taù and Olosenga, two of the Manua islands in the eastern end of the archipelago. This subsided after a fortnight's activity. A few months afterwards I was on board H.M.S. *Falcon* when soundings were taken over the spot where the volcano had been. We found a cone 180 feet above the bed of the surrounding ocean: the average depth of the sea around it being 120 fathoms, while the depth on the apex of the cone was only 90 fathoms. There has been no further eruption from this volcano up to the present time. Almost ever since this has been quiet, there has been great activity in the volcano of Nina Foou, in the neighbourhood of the Friendly group of islands.

Samoa, S. Pacific S. J. WHITMEE

THE ARITHMOMETER

MOST of our readers who have anything to do with calculations have heard of the above calculating machine, the invention of M. Thomas de Colmar. A few remarks, therefore, on its construction and operation may be of interest to those who have not seen this really useful calculating machine.

The instrument is of small size, the one which we are about to describe being only 22 in. long, 6½ in. wide, and 3½ in. deep.

We can best give an idea of the great saving of time effected by this instrument when we state that with it eight figures (tens of millions) can be multiplied by eight figures in eighteen seconds, sixteen figures be divided by eight figures in twenty seconds, and a square root of sixteen figures be extracted, with the proof, in less than two minutes.

Our illustration shows a top view of an arithmometer

the lid of the box being removed. It is constructed chiefly of a brass plate, A, furnished with eight slots, as shown; directly under these slots are mounted eight drums, each having nine elongated cog teeth of successively decreasing length; over each drum, and between it and the slot, is mounted a square shaft, on which slides a pinion wheel so as to catch any number of teeth on the drum. Each of these pinion wheels is moved by a button, *a*, of which there is one in each slot, the figures at the sides of the slots showing the proper position of each button *a*, for any work to be performed by the instrument.

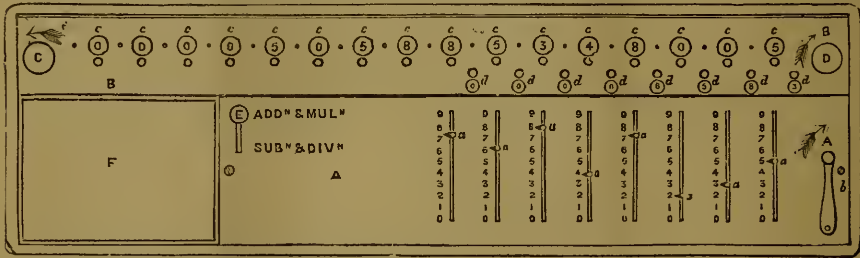
The cogged drums gear by bevil wheels with a long horizontal shaft, which is also in gear with the vertical shaft moved by the handle *b*, by which the instrument is worked. B is a moveable brass plate, which can turn and slide on a round bar-hinge at the back; in this plate there are sixteen holes, *c*, under each of which is a moveable disc numbered from 0 to 9, and arranged so that any one figure of each disc may be brought under its corresponding hole *c*. These discs have bevil wheels which gear with bevil wheels on the before-mentioned square shafts. The moveable plate B is also furnished with the holes *d*, having discs numbered from 0 to 9 underneath, and are for showing the number of turns of the handle, giving by this means the quotient in division, and showing the multiplier in multiplication. The knobs C and D are for bringing the figures under the holes *c* and *d* to zero before commencing an operation, and the knob E is for setting the instrument to work addition and multiplication, or subtraction and division. F is a small slate for memoranda.

Before further describing the working of the machine, we would remark that, if the knob E be placed at Add^{n}, each turn of the handle will carry the figures marked by the buttons *a*, under the indicator-holes *c*, or add them to the figures already under the holes *c*, while if the knob be placed at Sub^{n}, each turn of the handle will subtract from the figures under the holes *c*, the numbers marked by the buttons *a*.

Such being the general construction and principle of the machine, we will now proceed to give an example of its operation for multiplication, the operations for addition and subtraction being sufficiently explained in the preceding paragraph.

Thus, to multiply 76847235
by 6583

Mark the multiplicand on the plate A by the buttons *a*, as shown in the illustration; set the knob E at Add^{n} and Mulp^{n}, then turn the handle *b* three times for the unit figure of the multiplier, and three times the multiplicand, viz. 230541705, will appear under the holes *c* in the moveable plate B; this plate must now be raised, and moved one figure or station to the right, and the handle turned eight times for the second figure of the multiplier, and



Colmar's Arithmometer

6378320505 will appear under the holes *c*; move the plate B again to the right, and turn the handle five times for the third figure of the multiplier, and 44801938005 will be brought under the holes *c*; and finally, by moving the plate B once more to the right, and turning the handle six times for the last figure of the multiplier, the total product, 505885348005, will appear under the holes *c*, and the figures of the multiplier, viz. 6583, will appear in the holes *d*.

In division the operation is as simple as for multiplication, and is performed as follows: thus, to divide 414591904 by 4768, set up the dividend on the plate B, and the divisor on the plate A, commencing with the unit figure in each case to the right hand; place the knob E at Sub^{n} and Div^{n}, and move the plate B to the right until the second figure (from the left) of the dividend is over the first figure (4) of the divisor; turn the handle eight times, and 8 will appear in the quotient holes *d*, and will give the first figure of the quotient, while the dividend will now show 33151904, having been reduced by eight times the divisor, as in ordinary arithmetic; move the plate B one place to the left, and turn the handle six times for the second figure of the quotient, and the dividend will be further reduced by six times the divisor, and will mark 4543904; again move the plate, and turn the handle nine times, and after moving the plate B, and turning the handle five times and three times respectively, the holes *c* will all show noughts, and the quotient holes *d* will show 86953, which is the quotient required; if there had been any remainder, it would have appeared in the holes *c*.

Although by the ordinary limits of the machine a product of 16 places of figures and a quotient of 9 places of figures only can be obtained, yet by an intermediate record by the operator these limits may be virtually doubled for multiplication; while for division, provided the divisor does not exceed eight places of figures, the dividend and the quotient may be unlimited.

The use of the arithmometer in actuarial and other calculations has been shown in the papers read by Major-General Hannyngton and Mr. Peter Gray, F.R.A.S., F.R.M.S., respectively at the Institute of Actuaries (see the Journal of the Institute of Actuaries, p. 224, vol. xvi., and p. 249, vol. xvii.); and Mr. Thomas T. P. Bruce Warren, in a paper read before the Society of Telegraph Engineers, has shown the application of the instrument to electrical computations.

The Arithmometer is now, we believe, used in many Government Offices, in nearly all the Life Insurance Offices in England, in several Observatories; Sir W. Thompson, Prof. Tait, Prof. Galbraith, and Dr. Ball, also use them in the Universities and Colleges with which they are respectively connected.

The instrument can be seen, and all information obtained, of Mr. W. A. Gilbee, of 4, South Street, Finsbury, who, we understand, is sole agent for the Arithmometer.

ON THE SCIENCE OF WEIGHING AND MEASURING, AND THE STANDARDS OF WEIGHT AND MEASURE *

III.

Imperial Standard Pound

THE standard unit of imperial weight is the avoirdupois pound of platinum, constructed under the superintendence of the Commission for Restoration of the Standards. The mode of constructing this new standard

Fig. 4.—Form and size of the lost Standard Troy Pound.

of weight, together with full details of all the scientific processes employed, have been described by Prof. W. H. Miller, to whom its construction was more immediately entrusted. A drawing of the imperial standard pound has already been shown in Fig. 1.

For constructing this standard, the first point to be

Fig 5.—Queen Elizabeth's Standard Troy Pound of eight and four ounces

determined was the exact weight of the lost standard Troy pound, from which the weight of the new standard Avoirdupois pound was to be derived. Upon investigation, this proved to be the most difficult problem to be solved by the Commission. The old standard had been constructed in 1758, together with two similar pounds, under the direction of the Parliamentary Committee of that year. It is stated to have been composed of gun metal, but unfortunately no record exists of its volume or density, and it is not probable that it was ever weighed in water. An accurate drawing of the lost standard pound had been made in 1829 by Captain Nehus, who measured its dimensions with the greatest care. (See Phil. Trans. 1836, p. 361.) It very nearly resembles a Troy pound now in the Standards Department, which was constructed at the same time, and is said to be the original from which the lost Standard was made. Its form and size are shown in Fig. 4.

When the Troy pound was constructed under the direction of the Committee of the House of Commons in 1758, it was made as nearly as possible of the genuine weight of the Troy pound according to the ancient Standard. For this purpose comparisons were made of the Exchequer Troy Standards with each other, and with other Troy standards belonging to the Mint and the principal scale-makers. At the period when the Troy pound of 1758 was constructed, there existed no distinct Standard Troy Pound at the Exchequer. The Exchequer Troy Standards of Queen Elizabeth, which were the legal standards in 1758, consisted of a binary series of Troy

Fig 6.—Platinum Troy Pound, RS, of the Royal Society.

Fig. 7.—Platinum Troy Pound, T, of the Standards Department.

The form and size of the two platinum Standard Troy Pounds, RS and T, are as follows:—RS being a truncated pyramid surmounted by a knob, T cylindrical with a groove. The length of the side of the base of RS is 0·95 in., the total height 2·66 inches; the diameter of the base of T is 1·125 inch, the height 1·07 inch.

ounces from 258 oz. to $\frac{1}{8}$ oz., in the form of cup weights, fitting into each other. To obtain a Troy pound it was necessary to take the two Exchequer Standard weights of 8 and 4 oz., represented in Fig. 5.

The two other Troy pounds constructed in 1758 were found by the Commission to be in existence, as well as two similar Troy pounds made at the same time and bearing similar marks, though all differed slightly in their dimensions, as well as in volume and weight. They were all in good preservation and were carefully examined by Prof. Miller, but there was no satisfactory evidence of their having been accurately compared with the lost standard so as to identify its weight, and thus to render them available for determining the proper weight of the new standard. One of the two last-mentioned pound weights (denoted as O by Prof. Miller) is shown in Fig. 4. This weight was purchased by the Commission, and is now deposited in the Standards' Department. It differs very slightly in its dimension from the lost standard, as shown above, and its weight in air was computed by Prof. Miller to be 5759·85625 grains of the lost standard.

For ascertaining the exact weight of the lost standard

* Continued from p. 309.

pound, the following weights, which had been accurately compared with it, were examined :—

The brass Troy Exchequer Standard pound, constructed in 1824 under the superintendence of Capt. Kater, and legalised as the official Standard ;

Three similar brass pounds, constructed for the Cities of London, Edinburgh, and Dublin ;

A platinum Troy pound and two brass pounds belonging to Prof. Schumacher ;

The platinum Troy pound of the Royal Society.

It was found, however, from examining the results of several weighings of the brass Troy pounds that great discrepancies existed, attributable to the effect of oxidation or other causes. It was consequently resolved to rest entirely for evidence of the weight of the lost standard on the comparisons of the two platinum Troy pounds ; denoted by Prof. Miller as Sp and RS. These two platinum weights had been constructed in 1829, and were intended to be equal to the lost Standard (denoted as U) when weighed in air. Each of them had been compared with V by Capt. Nehus at Somerset House in 1829, with the following results :—

Mean of 300 observations, Sp = U − 0·00857 grain, (mean t = 65°·62 F. b = 29·722 in.)

Mean of 140 observations, RS = U − 0·00205 grains, (mean t = 65·73 F. b = 29·806 in.)

The density of Sp had been determined by weighing it in water, to be 21·1874, and it was found to displace 0·32544 gr. of air of the stated mean temperature and atmospheric pressure. The density of U had never been determined, but it was assumed to be of the same density as one of the Troy pounds constructed at the same time, viz. 8·151, which is nearly the average density of brass and bronze weights, and to have therefore displaced 0·84646 gr. Whence in a vacuum Sp = U − 0·52959 gr.

The density of RS also had not been determined by weighing in water, but it was assumed to be of the same density as Sp, and therefore to have displaced 0·32629 gr. of air, whilst U displaced 0·84865 gr. Whence in a vacuum RS = U − 0·52441 gr. The mean value of the lost Standard Troy pound thus determined through Sp and RS, was the basis upon which the new Standard Avoirdupois pound was to be constructed. As a preliminary operation, a new platinum Troy pound, denoted as T, was constructed very nearly equal in weight to Sp and to RS, and taking the mean of 286 comparisons of T with Sp, and of 122 comparisons of T with RS, it was found that in a vacuum

T = Sp + 0·00105, whence T = U − 0·52851
T = RS − 0·00429, whence T = U − 0·52870

From the mean of these two results, giving to the first twice the weight of the second, in consequence of Sp having been compared about twice as many times with U and with T as RS was compared, it was finally determined that in a vacuum

T = U − 0·52857 gr., or = 5759·47143 grs.

It was also found that in air t = 65° 66 F. b = 29·753° which was the mean of the comparisons of Sp and RS with U, and was adopted by Prof. Miller as the standard air,

T = U − 0·00745 gr.

It should be observed that all the standard Troy pounds were intended to be of their true weight in ordinary air, whilst the new standard imperial avoirdupois pound was to be made of its true weight when weighed in, or reduced to, a vacuum.

The next process was to determine the weight of the new avoirdupois standard pound, of 7,000 grains from the Troy pound T of 5,760 gr., and for this purpose four new platinum weights of 1,240 gr. each were constructed, all accurately verified in terms of T, and by employing other platinum weights of 800, 500, 400, 80, and 40 gr., the true weight in a vacuum of each of the 1,240 gr. weights was separately determined by numerous comparisons with T and with each other as follows :—

	Grains.
A =	1239·88622
B =	1239·88605
C =	1239·88597
D =	1239·88580
Mean =	1239·88601
T + Mean =	6699·35744

It thus required only a weight of 0·64266 gr. to make up the full weight of 7,000 gr. The approximate weight 0·645 gr. was obtained from T in the following manner. By comparisons with the 40 gr. platinum weights, two platinum weights of nominally 20 gr. each, were found to weigh 19·998 gr. each, from which were derived W = 12·901 gr., V = 6·0451 gr. From V was derived Q the mean of ten weights of platinum wire, and equal to 0·645 gr. very nearly. It will be shown, hereafter, in describing the mode of weighing with a scientific balance, that small differences between two Standard pound weights of less than 0·1 grain are ascertained by the index scale of the balance. Means were thus afforded of determining the exact weight of 7,000 gr., which was the weight in a vacuum of the new standard pound, constructed of platinum, and denoted as PS. or Parliamentary Standard.

The weight of PS was actually determined by the mean results of 80 comparisons with each of the following sets of weights :—

	gr.			°		mm.
PS ≏ T + Q + A	− 0·002936	in air t.	=	19·47 C.	b. =	758·38
PS ≏ T + Q + B	− 0·001731	,,		19·19		759·31
PS ≏ T + Q + C	− 0·001621	,,		18·83		754·38
PS ≏ T + Q + D	− 0·000774	,,		19·63		764·43

Mean of all,

PS = T + Q + ¼(A + B + C + D) − 0·00177 gr. in air t = 19°·28 C. b. = 759·12

The density of PS was determined by weighing in water to be 21·1572, and that of T and the smaller platinum weights to be 21·1661. PS consequently displaced 0·397 gr. of air, and T + Q + A displaced 0·39727 gr. Hence

PS = 7000·00093 grains of which U contained 5760.

Having arrived at this very close approximation to the desired weight of the new standard, it was resolved by the Commission that PS should be constituted the new Imperial Standard pound, and be consequently deemed to contain 7000·00000 grains of the new standard.

Four similar platinum pounds were also constructed, and their weight in terms of the new standard PS accurately determined. These were intended as auxiliary Standards of Reference, with the view that either of them might replace PS, in case of its destruction or damage. They were termed Parliamentary Copies (P.C.), and were deposited as follows :—

PC, No. 1, at the Royal Mint.
PC, No. 2, with the Royal Society.
PC, No. 3, in the Royal Observatory at Greenwich.
PC, No. 4, immured in the New Palace at Westminster.

Thirty-six other standard pounds of bronze gilt were also constructed, and their standard weight, both in a vacuum and in the standard air, adopted by Prof. Miller, was accurately determined, as well as the densities of all the new standard pounds. These gilt bronze pounds were distributed amongst different countries and public institutions of this country.

All the numerous weighings, both in air and in water, of the new standard pounds for determining their weights and densities were made by Prof. Miller himself, and full details of all these operations are given by him in his "Account

of the Construction of the new National Standard of Weight."

The new imperial standard pound is of the true weight of an avoirdupois pound when in a vacuum. The principal advantage of the metal of which it is composed (platinum), consists in its not being affected by oxidation, which would unavoidably alter its absolute weight. But platinum has this disadvantage, if used as the material of a standard for regulating ordinary weights of precision made of brass, viz. that when weighed in air against a brass or bronze standard weight of so much greater volume, although of equal weight in a vacuum, its apparent weight is always about half a grain greater than that of the brass or bronze standard. To obviate this disadvantage, the weight in standard air of all the bronze Standard pounds verified by Prof. Miller were computed by him, *not in terms of the platinum standard pound, but of an ideal brass commercial standard pound, denoted by him as W.* He assumed W to be of the same density as the lost standard, and of the average density of brass or bronze. In standard air, $t. = 65^{\circ}{\cdot}66$, $b. = 29{\cdot}75$ in. PS with a density of 21·1572 displaced 0·39644 grain of air, and W was assumed to displace 1·03051 grain. And as the official standard weights, by reference to which all commercial weights are verified, are made of brass or bronze, it was intended that they also should be regulated by their weight in air when referred to the brass commercial standard W. This has in fact been done. The only change since made has been under the sanction of the late Standards Commission, by which the standard air recited in the Act of 1824 for determining the weight in air of a cubic inch of water, viz. $t. = 62^{\circ}$ F., $b. = 30$ in. has been substituted for that adopted by Prof. Miller in consequence of its being the air in which the weight of the lost standard pound had been most accurately determined. The object of this change was to adopt one uniform normal temperature and barometric pressure for all standard purposes. In the new standard air ($\log \Delta = 7{\cdot}0852825 - 10$), PS displaces 0·40282 gr., and W, with a density of 8·1430, displaces 1·04706 grain of air.

H. W. CHISHOLM

(*To be continued.*)

THE TUSCAN MEMORIAL TO GALILEO

VILLARI, in speaking of Savonarola, and the men of his time, says :—"The world stood aghast at this new race of Titans, who arose to fight with the old idols, and it soon began to oppress them ; but it worships their remains and lingers in their footsteps." And this is literally the case : the descendants of those Italians who burnt Savonarola at the stake, preserve, with religious care, the cell in which he wrote, morsels of his monkish garments and of his hair, his manuscript notes, indeed every memorial that remains of him. The custodian who showed us these remains, together with a picture representing Savonarola at the stake in his own Piazza della Signoria, of Florence, abused Alexander VI. and the Inquisitors, and the whole body of ecclesiastics concerned in the matter, so roundly and so fiercely, that we were led to wonder what manner of Catholic he could be ; and to compare the Catholicism of 1872 with that of 1472. Thus, too, Galileo, persecuted during his lifetime, is now almost worshipped : the Tuscans have built him a shrine worthy of a saint ; in the inscription on his house at Arcetri, they call him *Divinus Galilæus ;* and in the shrine itself they have preserved, after the manner of a saintly relic, one of his forefingers which was detached from his body when it was removed from the chapel of SS. Cosmo and Damianus to Santa Croce. This relic is preserved in a small reliquary urn, upon the base of which is the following inscription written by Thomas Perelli :—

"Leipsana ne spernas digiti quo dextera cœli
Mensa vias nunquam visos mortalibus orbes
Monstravit, parvo fragilis molimine vitri
Ausa prior facinus cui non Titania quondam
Suffecit pubes congestis montibus altis
Ne quidquam superas conata ascendere in arces."

Again we have *Via Galileo* and *Biblioteca Galileina.* The Pisans point with pride to the *Lampada Galileina* in their Cathedral, and honour his statue in their University ; and these are the descendants of the men who paid Galileo tenpence a day for his services in the University ; who made him abandon his professorship because he proved that Aristotle was not infallible ; and who said derisively to his followers—"Ye men of Galilee, why stand ye gazing up into heaven ?" or, as Ponsard has it :—

"Ecoutez ce que dit l'Apôtre : *Dans les cieux*
Pourquoi Galiléens, promenez-vous vos yeux ?
C'est ainsi que d'avance il lancait l'anathéme
Contre toi, Galilée, et contre ton système."

The Tuscan Memorial to Galileo is in Florence, in the *Museo di Fisica e di Storia Naturale.* It is entirely the work of Tuscans, and is said to have been constructed at a cost of 1,000,000 lire (nearly 40,000*l.*) It consists simply of a vestibule, from which opens a small rectangular hall, with a semicircular tribune, in which is placed the statue of Galileo, by Prof. Costoli. The interior of the hall is entirely lined with white marble, and with frescoes in admirable taste. The frescoes in the vestibule represent Leonardo da Vinci in the presence of Ludovic Sforza, Duke of Milan, to whom he is making known some of his great inventions. Apropos of this, there exists in the Ambrosian Library, in Milan, a large folio full of MSS. notes, and drawings, by Leonardo da Vinci, which the courteous director of the library is always willing to place in the hands of interested strangers, and which well repays the most careful examination. Some of the sketches of hydraulic apparatus, appeared to us to be worthy of minuter study than they appear to have received. The opposite fresco of the vestibule represents Volta explaining his invention of the pile to the members of the French Institute, in the presence of the first Consul, Napoleon, and Lagrange. In the vestibule are also placed marble medallions of Leo Baptista Alberti, and Baptista della Porta. A fresco in the hall by Bezzuoli, represents Galileo lecturing in Pisa, on the laws of falling bodies. This is a really striking and well-conceived painting : Galileo in his professorial toga stands by the long inclined plane, showing his results to his colleague, Mazzoni. In the foreground is a professor in a monastic habit, kneeling near the inclined plane, and counting the time of descent of the falling body, by the beats of his pulse. Young students are pressing round Galileo, in order, if possible, to aid him in his experiments ; while on another side the Aristotelian professors are looking on with derision, and searching in vain in the writings of the Peripatetic for explanations of the new facts. In the background appear the cathedral and the leaning tower. The whole conception is noble and spirit-stirring, and one longs for a similar treatment of other great discoveries in science :—Davy discovering potassium, Faraday obtaining the first magneto-electric spark, and magnetising a ray of light. The opposite painting represents a meeting of the *Accademia del Cimento:* the patron of the Society, the Grand Duke Ferdinand II., is eagerly watching an experiment which is being made by Redi, Viviani, and Borelli, on the apparent (to them real) reflection of cold by a parabolic mirror :—one of the rough spirit thermometers recently invented by the Academy, is placed in the focus of the mirror, and a block of ice is used as the source of cold.

The three frescoes in the Tribune immediately around the statue of Galileo, represent three notable events of his life : in the first he is seen intently watching the swinging of a lamp in the Cathedral of Pisa ; in the second we see him in the act of presenting his telescope

to the Venetian Senate; and in the third he is represented as an old man, in his house at Arcetri, dictating the geometrical demonstration of the laws of falling bodies to his disciples Torricelli and Viviani. On the arch above the statue, the astronomical discoveries of Galileo—the Italians claim for him the Milky Way, the Nebula of Orion, the Phases of Venus, the Mountains of the Moon, the Satellites of Jupiter, the Solar Spots, and the Ring of Saturn—are represented very effectively on a blue ground. Bas-reliefs in marble on the pillars of the arch represent his terrestrial discoveries—his countrymen claim for him the Pendulum, the Hydrostatic Balance, the Thermometer, the Proportion Compass, the Keeper of Magnets, the Telescope, and the Microscope. Beneath the frescoes and around the statue are niches, containing some of Galileo's instruments, his telescope, an objective made by the astronomer himself, a proportion compass, and a magnet, with a keeper which he constructed for it. Immediately surrounding the statue we notice the busts of his most celebrated followers, Castelli, Cavalieri, Torricelli, and Viviani. In the hall there are six cases containing old apparatus, chiefly that of the Academy of Cimento. The various thermometers figured in the "Saggi di Naturali esperienzi" of the Academy are here to be seen; the vessels they used for showing the incompressibility of water; hygrometers; together with astronomical and geodesical instruments. Here, also, is the large burning-glass constructed by Bregaus of Dresden, employed by Averani and Targioni in their experiments on the combustion of the diamond, and afterwards employed by Sir Humphry Davy. The various inventions and discoveries of the Academy are shown in bas-relief on the pillars of white marble.

The memorial is altogether worthy of the man, and of the fine taste of the Florentines. It is, perhaps, the only *sanctuaire scientifique* which exists, but we may hope that the example of the Florentines will be followed in this and other countries. The Milanese have recently bought the collection of apparatus and the MSS. of Volta (for a sum, we believe, of 100,000 lire); a suitable museum for them will, no doubt, soon be fitted up. It is much to be wished that Faraday's apparatus could be collected together in one place, as a memorial to the man. This reminds us that soon after the death of Faraday a subscription was set on foot for the purpose of providing some suitable memorial, but we are unable to remember whether the designs of the committee were fully carried out, and whether the subscription attained the desired amount; if not, it is to be hoped that the matter will be kept well before the public.

We have spoken above of the discoveries attributed to Galileo by his countrymen. We are inclined to think that some of his claims have been pressed too far; but on such a subject an almost endless controversy might be carried on, for we may remember that even the invention of the telescope has been claimed for others of his own countrymen (Antonio de Dominis and Baptista Porta), and by the Dutch; and the invention of the thermometer has been attributed to Cornelius Drebbel, Sanctorio of Padua, and others. But if we put all this aside, Galileo still stands out pre-eminently as one of the fathers of experimental philosophy: he did not create it, but he introduced a taste for it, and enlarged it, and he possessed in an eminent degree the true spirit of philosophical inquiry, the ardent love of research, the "Provando et Riprovando" which the Academy of Cimento adopted as its motto.

G. F. RODWELL

THE SPHYGMOGRAPH AND THE PULSE

THERE are few valuable instruments or methods of research which have been brought before the scientific world under circumstances less auspicious than one, the inventor of which, the illustrious M. Marey, has quite recently visited this country. The sphygmograph, shortly after its first construction, was introduced into this country as an instrument which gave promise of being an invaluable aid in diagnosis, and of such universal applicability as the stethoscope and thermometer. Nevertheless, after an existence of more than ten years, it may be said that the general impression respecting it is that it is a failure, that it has not answered its expectations, and that it may as well be put aside, together with other curiosities of the physiological laboratory. How this result has come about is not difficult to discover. The instrument is a complicated one, and its indications are even more so. The stethoscope, when introduced, gave results at first sight palpable to the most ordinary minds, and the amount of mechanical knowledge necessary for the comprehension of some of its most striking results scarcely exceeded that of the principle of the common pump. But with the sphygmograph the case is different. Its indications are so detailed and so precise that before they can be understood, it is absolutely essential that several intricate and elaborate problems of hydrodynamics and physiology should be thoroughly investigated, and more than one of these have not, we are surprised to say, yet left the hands of the mathematicians in any decided form. How then is it to be expected, as it has been by many, that the sphygmograph should be found a valuable assistance in the diagnosis and prognosis of disease, before the physicist and physiologist can give an explanation of the language in which it appeals to them? There is no doubt that the instrument must be in the hands of the student of the healthy body for some time to come before its true value in the elucidation of disease will be appreciated; and all additions to our knowledge concerning it must be carefully weighed.

In a thesis for the M.D. Cantab.,* Dr. Galabin has published several results of his sphygmographic work in the study of renal disease, and what is more to the point on the present occasion, he gives his own ideas as to the analysis of the same trace in health. The fact of the author's being an accomplished mathematician, as well as a student of biology, gives more than ordinary weight to his remarks, and enables him to put several points in a light which is clearer and more precise than usual.

The author does not enter fully into the reasons in favour of his views, and does little more than simply state them; but as they differ in some respects from those generally accepted, they present features of interest to workers on the subject. He is one of those who consider the trace as it appears on the recording paper as a decidedly duplicate phenomenon, resolving it into the true pulsation, together with the oscillations of the lever, which necessarily result from the momentum acquired by its sudden movement. This he illustrates by superimposing on an ordinary pulse curve, as taken by the sphygmograph, an ideal one, such as, according to his conception, it would be if the instrument correctly followed the changes in the diameter of the artery under observation; the latter being little more than a uniform rapid rise followed by a similar but slower fall, that is slightly broken by the "dicrotic" wave, which is produced by the closure of the aortic semilunar valves. The excessive height of the primary rise is supposed to be due to the powerful impulse given to the lever at the commencement of the flow of fluid in the artery; and the small secondary, or "tidal" wave, which occurs just before the "dicrotic," is supposed to indicate the true arterial expansion, which the lever meets on falling from the height of its impulse. We quite agree with part of this explanation, being fully convinced, from many reasons, that the primary rise, or so-called "percussion" wave, is not a percussion wave at all in the ordinary

* "On the Connection of Bright's Disease with Changes in the Vascular System." By A. L. Galabin, M.A. M.D., Fellow of Trinity Coll, Camb.

acceptation of the term; in other words, that it does not result from the shock produced by the opening of the aortic valve, but that it is coincident with the flow of liquids, one reason being, as the author remarks, that the most violent impulse in an artificial model or schema of the circulation so communicated, as not to cause any flow of liquid, produces no upstroke, but only a slight quivering of the lever. However, that the primary oscillation of the lever in a sphygmograph trace is not, in a great measure, a genuine representation of the movements in the artery, it is equally impossible to believe, for in very slow pulses, where the main rise is not very decided, this wave is particularly pronounced, being gradual in its rise, and more gradual and paraboloid in its fall. It is also seen equally clearly by employing a reflecting sphygmoscope, in which the ray of light which acts as the long arm of the lever, has no weight, and consequently cannot produce any oscillation. Another great objection is that the notch between the first and second (the percussion and the tidal) waves always occurs at the instant at which the aortic valve closes at the heart,* the time it appears after the commencing pulsation *varying* with the length of the pulse-beat. In fact, the tendency of all observations is to make it evident that the second or tidal wave is a post-systolic act, being the oscillatory indication of the secondary tidal wave, which appears as such in the dicrotic rise, and originates from the closure of the aortic valve, as Dr. Galabin agrees with most in thinking; though Dr. Sanderson holds the very different view that the second beat is a restoration of equilibrium which takes place by increase of pressure towards the heart and diminution towards the periphery, a consequence of the sudden projection towards the capillaries of the blood during the systole.

Dr. Galabin remarks that, "if the sphygmograph used have a secondary spring to keep down the long lever, the tidal wave may be replaced by two or even by a jagged line. Such a spring is better omitted, because it is apt to introduce oscillations of its own." It is this idea which has misled him. Tracings taken as he proposes appear much in favour of his explanation, but they are so because they are in reality less truthful than they might be. We have never seen the least indication of any imperfections caused by the employment of the small spring, but we have seen the "percussion" wave divided into two by it in very slow pulses, the former being a small true shock-rise, and the latter the real primary rise.

In conclusion, we cannot refrain from quoting a remark of Dr. Galabin, which, from the precise way in which it sets the question referred to at rest, is worthy of being quoted in every text-book. Referring to the rhythmical contraction observed by Wharton Jones and Schiff in the wing of the bat and the ear of the rabbit, and its supposed influence in assisting the circulation of the blood, he remarks, "Now a peristaltic wave in a tube would tend to produce a current in the liquid of its own velocity, and it would, therefore, accelerate a slower current, but retard a quicker one. Therefore, no peristaltic wave could accelerate the arterial stream, unless it travelled with the velocity of the pulse-wave. It is thus evident that no such slow rhythmical motions as have been observed could assist the arterial flow. And it is inconsistent with the usual character of involuntary muscle to suppose it capable of transmitting a very rapid wave of contraction. The arteries themselves indeed, when made to contract by artificial stimulus, do so slowly and gradually."

A. H. G.

AMERICAN EXPLORING EXPEDITIONS IN THE GREAT WEST

THERE are several important expeditions more or less employed upon scientific work in the least known portions of the Western territories. From some of these parties, a considerable amount of fragmentary information comes at irregular intervals; but in other cases the explorers prefer to withhold details as to their movements and work, whether scientific or otherwise, till after their return, when their report can be prepared officially. There is, however, a general and widespread interest taken in these explorations. It seems desirable for the sake of a clear understanding of news from time to time received, that a general *résumé* of the status and work of at least the more prominent expeditions should be presented.

What is known as the Yellowstone Expedition will first be mentioned, because in size it is much the most formidable. It proceeds through a region where it is deemed advisable to strike terror among hostile savages, and with that view has a military force of 1,900 men. Its movements also have reference to the establishment of two new military posts in the north-west, for which purpose Congress has appropriated 200 000 dollars. The force serves as an escort to surveying parties of the Northern Pacific Railroad, with reference to its completion from the town of Bismarck on the Missouri River in Dakota—about the centre of that territory, and near the 101st parallel west of Washington—to the Rocky Mountains; a distance of between 500 and 600 miles, on a line drawn in general east and west, and south of 47° N. lat.

This line may be divided into three parts; (1) from the Missouri River to the Yellowstone, about 200 miles, coming into the territory of Montana; (2) along the Yellowstone River about 100 miles; (3) thence west-ward, reaching the Rocky Mountains south of the town of Helena. At the date of latest advices, the expedition had passed over the first division, and was on the banks of the Yellowstone. The navigability of that river had just been demonstrated by the successful ascent of a steamboat, built at Pittsburg for the purpose, which brought supplies from Fort Buford.

Of the scientific party accompanying the Yellowstone Expedition, the following names may be mentioned:—Dr. J. A Allen, of Cambridge, Mass., in charge of zoology, botany, and palæontology, and chief of the scientific party; Dr. L. R. Nettre, mineralogist and geologist; W. R. Pywell, of Washington, photographer; E. Konipucky, of the Museum at Cambridge, artist; and C. W. Bennett, taxidermist.

The Hayden Expedition, as that under the management of Dr. F. V. Hayden is generally termed, might be more properly designated as the United States Geological and Geographical Survey. It has a much larger scientific staff than any of the other expeditions. Its history dates from 1867, when what was then the territory of Nebraska was the subject of a survey by the United States, Prof. Hayden being appointed chief geologist to the survey under the Act of Congress by which the undertaking was authorised. The next year the survey was extended into Wyoming Territory, and in 1869, into Colorado and New Mexico. In 1870, a more careful survey of Wyoming Territory was made; and in 1871, portions of Montana, including the natural wonders of the Yellowstone region, became the subjects of exploration; ultimately resulting in the setting apart as a public pleasure-ground of the Yellowstone National Park, a district of 3,575 square miles. The survey of 1872 reached the region of the Yellowstone by separate routes of two divisions, of which one proceeded from Fort Ogden, Utah, and passed up the Valley of the Snake River in Idaho Territory; the other started from Boseman, a town in Montana near the Rocky Mountains, and on one of the Upper Forks of the Missouri River. The appropriations for this series of surveys have been increased year by year, starting with 5,000 dollars in 1867, and rising to 75,000 dollars for the survey now taking place.

The district of this year's operations may be specified as the eastern half of mountainous Colorado, includes about 32,000 square miles, and is bounded east by long. 104° 30′, north by lat. 40° 25′, west by long. 107°, and south by the southern boundary of Colorado, lat. 37°. It is divided for the purposes of the survey into three parts by latitude lines 38° 30′ and 39° 30′; the northermost being called the "Middle Park Division," the middle one the "South Park Division," and the southern one the "San Luis Division." The examination of the gold and silver mines of the region, and the measurement of its mountains, are among the more important duties of the survey. Unusual prominence is given to procuring pictures by photographs and otherwise.

The camp was organised at Denver College in May; the expedition started thence July 1, numbering 41 men. The season has been unusually favourable, the streams being low and but little snow or rain falling. The location of the camp at the latest advices was on the eastern slope of the Rocky Mountains, at the head-waters of the Platte, Arkansas, and Blue Rivers. Accurate measurements of some of the more prominent peaks, among which are Pike's, Long's, Evan's, Gray's, Lincoln's, and the Holy Cross, have been obtained. The views from these summits where the snow melting on one side flows to the Atlantic, and on the other to the Pacific, are of vast scope and magnificence. There were in sight from one point by actual count, 150 peaks of not less than 13,000 ft., and at least 50 of 14,000 ft. in height. By the middle of July 150 stereoscopic views, and 50 11 × 14 in. negatives of this scenery had been secured. The mountains have, very generally, at a depth of 50 to 200 ft. from their surface, a limestone stratum 30 to 50 ft. thick, containing silver and lead, yielding on the average in the best mines 250 to 300 ounces of the former metal, to the ton of ore. The carboniferous and silurian rocks identified are said to contain rare fossils. The entomologists of the expedition have classified no less than 227 different kinds of grasshoppers. The direction of march projected at last accounts was to be toward the valley of the Upper Arkansas River and the unexplored region beyond.

There are more than 20 scientists taking actual part in the expedition: among them may be mentioned Dr. F. V. Hayden, geologist-in-chief; Mr. J. T. Gardner, chief geographer, who has attained great reputation in his connection with previous geodetic surveys in Colorado and on the Pacific coast; Mr. Marvine, geologist of the Middle Park Division; Mr. Henry Gannett, meteorologist and astronomer, and topographer, in charge of the South Park Division; Mr. W. H. Jackson, in charge of the photographic party; Dr. Endlich, geologist; Lieut. W. L. Carpenter, naturalist; Mr. Seward Cole, ornithologist; Mr. J. M. Coulter, botanist; Dr. A. C. Peale, geologist; Prof. W. D. Whitney, of Yale College, who is writing a series of interesting letters concerning the work, to the *New York Tribune*.

On some accounts the expedition of Prof. O. C. Marsh, sometimes known as the Yale College Expedition, because the fossils collected are sent to that institution, ranks next in importance. This is purely a private undertaking, at the expense of the persons composing the expedition. The United States Government furnishes a small but sufficient military escort. The reports are published under Government auspices. This is the fifth of a series of expeditions similarly undertaken by Prof. Marsh, has no reference to surveying or topography, and is devoted exclusively to research for the remains of extinct vertebrates in the tertiary and cretaceous formations. The districts explored hitherto with such remarkable success will probably supply the fields of the present undertaking. The directions previously taken were as follows:—

First expedition, in 1868, to Lake Como, Wyoming Territory. Second, in June, 1870, to the Loup Fork River, in Nebraska; the Bad Lands east of the Black Hills and between the North and South Forks of the Platte, in Wyoming and Colorado; and the Great Basin of the Green River, southward from Fort Bridger, bordering Utah. There were also minor trips during this expedition to Green River, in Wyoming, and to the Smoky River, in Kansas, which were productive of valuable results. The third expedition started in the summer of 1871, and again explored the Smoky River region in Kansas, the Green River Basin, above mentioned, and investigated two basins, likewise of the Tertiary age, one in Idaho and the other in Oregon. The fourth was a trip with a comparatively small party in the autumn of 1872. It concentrated at St. Louis, went to Fort Wallace by way of Kansas City, and, receiving escort, proceeded to Smoky Hill Fork. On this expedition some explorations were made near Cheyenne, and several days were spent in researches, with varying success, at Crow's Creek, Colorado.

At the most recent dates the present expedition, leaving North Platte Station on the Union Pacific Railroad, had made a nine days' march through a desert country, undergoing great hardships; had reached the Niobrara River, made investigations on both its banks for more than 100 miles below the mouth of Rapid River, and had returned, laden with fossils, to Cheyenne, expecting to make the next start from Fort Bridge in Wyoming Territory. This expedition may extend its researches, as Professor Marsh informed the writer, to the Pacific Coast, and is not expected to return till late in the autumn.

The expedition known as the Wheeler Exploration Party is under the management of the U.S. War Department, Bureau of Engineering. Its chief is Lieut. G. M. Wheeler, of the U.S. Engineers. The operations of the present season will consist of exploration and survey west of the 100th meridian and south of 40°, principally in New Mexico and Arizona, down to the borders of Mexico. The following are named amongst the scientific force:—Messrs. Henry Leubbers, G. Thompson, J. J. Young, and E. Somer, topographers; G. R. Gilbert, E. E. Howell, J. J. Stevenson, and Oscar Loew, geologists; H. W. Henshaw and John Wolfe, naturalists; B. Gilpin, meteorologist; J. H. Clarke, Dr. F. Kampf, W. W. Marryatt, and Prof. H. B. Herr, astronomical observers. The establishment of an astronomical observatory, substantially built of brick, having three observing-rooms, at Ogden, Utah, will form part of the labours of this expedition, which concentrated its forces to start from Denver in June last.

There is an expedition under command of Capt. W. A. Jones, of the U.S. Engineers, which started from Omaha on the 2nd of June. Its objects are mainly topographical, having direct reference to the Yellowstone National Park; but it may be extended to the Big Horn country, a wild region imperfectly known, and said to be fabulously rich in minerals, situated south of 44°, and between meridians 106 and 108. Among the scientific men attached to this party are Lieut. S. E. Blunt, astronomer; P. Le Hardy, topographer; Dr. C. C. Parry, botanist and mineralogist; and Mr. T. B. Comstock, of New York, geologist.

Whether there is a surveying party under Mr. Clarence King, geologist, still in the Wasatch Mountains, at work on the line of the 40th parallel; whether that of Major J. W. Powell has returned from its investigations having principal reference to the cañons of Colorado; and whether a party that went from Philadelphia—consisting principally of Prof. Joseph Leidy, palæontologist, Dr. Henry Chapman, zoologist, Mr. Joseph Willcox, mineralogist, all of that city, and Prof. Porter, of Easton, Pennsylvania, botanist—is still in the wilds of Wyoming and Colorado, the writer is unable, at the present date, to determine.

New York, Aug. 8

NOTES

FROM a private letter just received from Prof. Wyville Thomson, we learn that the *Challenger* left St. Vincent, Cape Verde Islands, on August 2, for Bahia, for the purpose of making her fourth section across the Atlantic. As it is now the middle of the rainy season, and as part of the course of the *Challenger* lies along the coast of Africa to the southward, the members of the expedition expect to be very uncomfortable for a time. On July 15 a very successful month's cruise from Bahamas was completed, some of the details of which we expect to be able to publish next week. "We are getting on first rate," the letter says; "the arrangements continue very complete and satisfactory."

THE French Association for the Advancement of Science opens to-day at Lyons, under the presidency of M. de Quatrefages.

THIS year's meeting of the Iron and Steel Institute opened on Monday at Liège, where the members received a most enthusiastic reception. The first meeting was held at the Academic Hall of the University, when Mr. Lowthian Bell, the President, delivered a speech, in which he warmly thanked the Belgian ironmasters for their friendly reception, and then spoke at length on various technical matters. On Tuesday a second meeting was held, when several papers were read. It was announced that the members were invited to hold their meetings next year in the United States. Many fêtes, receptions, and other entertainments have been got up for the members, who are also to visit the principal mines and iron foundries of the district. To-day the members are to be received by the King of Belgium at the Royal Palace in Brussels.

THE British Archæological Association commenced its yearly meetings at Sheffield on Monday, under the presidency of the Duke of Norfolk, who entertained the members, and others, at dinner in the evening. The members received a hearty welcome from the town, and have been visiting several places of interest in the neighbourhood. On Tuesday evening several papers were read in the Cutlers' Hall on Yorkshire archæological and antiquarian subjects. Among these was a paper by Mr. J. R. Planche, Somerset Herald, on "The Early Lords of Holderness," and one by the Rev. Dr. Gatty, on "The Town and Parish Church of Sheffield."

THE twenty-fifth annual meeting of the Somersetshire Archæological and Natural History Society commenced at Wells on Tuesday. The opening meeting was held at 12 o'clock at the Town Hall, the retiring president, Mr. W. A. Sanford, of Minehead Court, taking the chair. After a brief speech he resigned the presidency to Lord Hervey, the Lord Bishop of the diocese. In the report of the Council, the following subjects, among others, were referred to:—The druidical circles of Stanton Drew, the chambered tumulus of Stoney Littleton and Cadbury Camp have, through the influence of the Council, been enumerated in Sir John Lubbock's Bill for the preservation of public monuments. It is proposed to purchase the castle of Taunton as a museum for the rapidly growing collections of the society; 3,000*l.* are wanted. Mr. Ayshford Sanford, in urging the purchase of Taunton Castle, mentioned that it is the oldest fortress of English origin in the west of which the date is certain. It was built by King Ina, about the year 700, and has a Norman keep, and specimens of architectural additions of every date down to the Perpendicular. The earthworks are in good preservation. Mr. E. A. Freeman, D.C.L., in speaking on the question whether the next meeting should be held out of Somersetshire, said the study of the Church architecture of the district was incomplete unless it included Sherborne Minster at one extremity and St. Mary Redcliffe, Bristol, at the other. Sherborne, too, was the old bishopric out of which Wells was carved. After some routine business, the Bishop gave his address. He pointed out some peculiarities of Somersetshire as a county, its many double-named places, its number of small holders, and the absence of any old baronial seats.

THE *Gazette d'Augsbourg* contains some interesting details in connection with the recent meeting at Copenhagen of the Scandinavian Scientific Congress. This is the oldest of the many northern societies, having been instituted at Gothembourg in July 1839. Among the original members are the names of E. H. Œrstedt, J. F. Schouw, Forchhammer, E. Fries, Nilson, Berzelius, Hansteen, all men of the highest eminence in their own departments. The meetings of this Association are held alternately at longer or shorter intervals, in each of the three Scandinavian kingdoms, at Copenhagen, Stockholm, and Christiania, the kings of the countries always showing an active interest in the doings of the Association. At the recent—the eleventh—meeting at Copenhagen, the number of members was 400, the President being M. Steenstrup, who delivered the opening address in the presence of the King and Crown Prince of Denmark. The meeting was divided into ten sections, in each of which many papers were read; general meetings were also held, and several excursions made to places in the neighbourhood.

MR. SMITH, the leader of the *Daily Telegraph* Assyrian Expedition, gives in the *Telegraph* of Tuesday a number of interesting details of his work. He gives a translation of the tablet which relates the curious legend of the descent of Ishtar, the "daughter of Sin" (the moon-god), into the infernal regions. The boxes containing the more portable of the treasures exhumed by Mr. Smith have, after many hazardous adventures, safely reached this country. These, with several very valuable memorials purchased in Mesopotamia by Mr. Smith, and the expense of which the proprietors of the *Telegraph* have very generously charged themselves with, are now safely lodged in the British Museum. The heavier articles are expected to arrive in this country very shortly.

THE following among other exhibitors have received diplomas of honour at the Vienna Exhibition:—In the Mining Department: the Geological Survey Office, Calcutta. In Group 22: the South Kensington Museum, London. Educational matters: the National Educational Bureau, Washington; Dr. Leitner, Lahore, India; the Government of Massachusetts; and the Smithsonian Institution, Boston, U.S.

MR. G. F. RODWELL, Science Master in Marlborough College, has resigned the Lectureship on Natural Philosophy in Guy's Hospital.

WE should advise all connected with Science teaching in schools connected with the Science and Art Department, to obtain a copy of the new syllabus in the following subjects, just issued by the Department:—Subject XIV., Animal Physiology; XV., Zoology; XVI., Vegetable Anatomy and Physiology; XVII., Systematic and Economic Botany. From the Syllabus it will be seen that (*a*) Subject XIV, Animal Physiology, is altered in certain details. (*b*) Subject XV., has now become "Elementary Botany," being a modification of the former Subject XVII., Systematic and Economic Botany. (*c*) Subjects XVI. and XVII. together now form a new subject, Biology, into which the former subjects of Zoology and Vegetable Anatomy and Physiology are absorbed. The elementary stage is the same for both Subjects XVI. and XVII., the advanced stages of these subjects being respectively Animal Morphology and Physiology, and Vegetable Morphology and Physiology. As respects the existing qualifications of teachers for earning payments on the results of instruction, the deductions in those payments on account of the previous success of the pupil, and the prizes to the pupils—(*a*) Subject XIV., Animal Physiology, will be in no way affected by the change now made in the syllabus. (*b*) Subject XV., Elementary Botany, will be treated as if it were the same as the former Subject

XVII., Systematic and Economic Botany. (*c*) Subjects XVI. and XVII. will be treated as perfectly new subjects, except that all persons will be qualified to earn payments on results in those subjects who are now qualified in Subject XV., Zoology, and Subject XVI., Vegetable Anatomy and Physiology, and also all those persons who have obtained a class at the courses in Biology and Botany respectively for teachers at South Kensington. (*d*) As the elementary stage of Subjects XVI. and XVII. is the same, payments can only be made on account of a pupil's success in one or the other, and not in both. Payments for the advanced stage and for honours can be obtained in both.

THE following are the regulations for exhibiting Recent Scientific Inventions and Discoveries of all Kinds, at the International Exhibition of 1874:—Division III. Recent Scientific Inventions and Discoveries will consist of objects the excellence and novelty of which are considered by the Committee of Selection to be so great as to render it undesirable that their introduction to the public should be delayed until the proper year for the exhibition of their Classes of Manufacture in Division II. No objects will be admitted into Division III. which have been shown in previous International Exhibitions of this series, unless very important alterations or improvements have been added to them since the date of their previous exhibition. The latest day appointed for receiving objects in this Division is Wednesday, March 11, 1874.

THE Birmingham Natural History and Microscopical Society propose to undertake a novel and commendable enterprise in the shape of a marine excursion. The sub-committee appointed to consider the practicability of the proposal are of the opinion that if such an excursion be properly carried out, it cannot fail to be productive of interest and enjoyment to the members. Taking all matters into consideration, the sub-committee are of opinion that the South Coast of Devon is the most favourable for the proposed excursion; and if Teignmouth be selected as headquarters, it will allow of dredging and shore collecting in the vicinity, and in Tor Bay, and off Berry Head, as well as botanical and geological excursions in the neighbourhood, and (if time permits) visits to the wilds of Dartmoor and the beautiful and picturesque scenery of the River Dart, Holne Chase, Lustleigh Cleave, Becky Falls, &c. It is proposed that the excursions commence on Monday, September 1, which would allow six clear days dredging in the neap tides after the August new moon, and some shore collecting during the September full moon. A first-class yacht, with two men and a boat, can be hired for a very moderate sum, and the Midland Railway Company offer return tickets at very moderate rates with the privilege of staying in Devonshire for 17 days. Various members have undertaken to superintend the dredging, botanical, microscopical, and geological work, and altogether the arrangements proposed are very complete and seem likely to make the excursion a success. We hope it will prove so, and that the example of the enterprising Birmingham Society will be followed by others, either singly or in combination. Inquiries should be addressed to Mr. W. G. Blatch, Hon. Secretary, Green Lane, Small Heath, Birmingham.

THE Brighton and Sussex Natural History Society has determined to collect facts in connection with the Natural History of Sussex, for the purpose of verifying existing Lists, and preparing (with a view to ultimate publication) an authentic systematic record of the land and marine fauna and flora of the county. The Society will be much obliged to all who can render assistance in any or all of the following ways:—(1) By forwarding to the Society lists of such species as may have fallen under one's own *personal* notice; (2) by contributing facts relating to such points as *approximate* locality (in order to prevent the extirpation of rare species, the approximate, and not the exact, locality is asked for); whether rare, local, or common; accidental variations; apparent extinction and re-appearance; times of appearance; any noteworthy matters connected with the life history of species; and (3) by sending specimens to be deposited in the Brighton Free Museum or other Museums in the county. Communications will be thankfully received by Mr. R. Glaisyer, Honorary Curator, Dispensary, Queen's Road, Brighton; or by T. W. Wonfor, and Jno. Colbatch Onions, Hon. Secs.

SCHIAPPARELLI has recently published two very interesting memoirs, the one an elaborate historical monograph on "The Precursors of Copernicus," and the other on "Falling Stars."

SIGNOR AUGUSTO RIGHI, Demonstrator of Physics in the University of Bologna, has published a very interesting memoir, *Sul Principio di Volta* (Bologna: Tipi Gamberini e Parmeggiani, 1873). In this he discusses at great length Volta's theory of electrical excitation. A number of original experiments are given, and photographs of a new apparatus employed for them.

ENGINEERS have been busy on the estate of Mr. W. Gilford, at Dalby-on-the-Wold, aad other places in Leicestershire, investigating the allegation that the Midland coal measures extend in an almost direct line from near Leicester to Melton Mowbray, and through the Vale of Belvoir, embracing an area of many square miles. As the reports made are of a highly favourable character, and as the importance of having a coal-field close to the town of Leicester can scarcely be over-estimated, it is proposed to bore to a depth of 1,000 ft., and to divide the expense *pro ratâ* amongst the landowners. Several of those most interested have signified their desire to have the problem solved in the only practical manner. Mr. Harrison, of the Mining School, Nottingham, is of opinion that "coal exists under East Notts and East Leicestershire, there being an anticlinal fault throwing out all the measures in the western part of Notts, and throwing them all in on the eastern side. From this and other considerations" he is convinced "that there is an immense coal-field stretching along the county of Nottingham, by Bingham, through the Vale of Belvoir, as far as Melton Mowbray, and will be found at a workable depth."

AT the last monthly meeting of the council of the Victoria Institute, it was announced that seventy-nine new members had joined during the past seven months. It was also reported that in accordance with a resolution passed at the previous meeting the Institute had joined in the application made to the Government for adequate aid to the expeditions to observe the transit of Venus, more especially those so strongly urged by the Greenwich board.

THE valuable library of Conchological and other Natural History books belonging to the late Mr. Thomas Norris, of Preston, was sold by auction on July 30, by Mr. J. C. Stevens, for 322*l.* Mr. Stevens also sold, on Aug. 7, the library of the late D. H. Beaumont Leeson, F.R.S., of Bonchurch, for 580*l.*

THE recent earthquake in South America extended, it is stated, over 30,000 square miles.

THE following is from the *Gardener's Chronicle*:—"We learn that Baron von Mueller is about to retire from the directorship of the Botanic Garden, Melbourne. On scientific grounds this is much to be regretted, for no one has done so much as the Baron to forward the interests of Botanical Science and practical applications in Australia as he has done. We cannot profess to judge the circumstances which may have led to this step; but if, as is alleged in some of the Melbourne papers, 'the gardens are henceforth required more as an ornamental adjunct to the Vice-regal domain than as the centre of Botanical Science and experiment in Australia,' then undoubtedly the authorities manifest an ignorance of the proper functions of a botanic garden which is,

unhappily, not confined to Australia. Everyone must desire that the garden should not be a 'cheerless' 'scientific desert' at the same time it is equally clear that it should not be transformed merely into 'a pleasure-ground worthy of the name.' It is satisfactory, however, to learn that the Baron's services to the State will not be lost, that he will not suffer in pocket by the change, and that additional and much needed assistance will be given him."

THE *Canadian Ornithologist* is the name of a serial started last month, "with the object of making a monthly depository of facts, theories, and anecdotes relating to our feathered friends." Dr. Ross of Toronto is the editor. The first number leaves much room for improvement in its successors.

THE last number of the *Journal of the Society of Arts* contains a report by Dr. R. J. Mann, on "Recent Scientific Inventions and New Discoveries at the International Exhibitions."

THE following is the list of candidates successful in the competition for the Whitworth Scholarships, 1873 :—Samuel Dixon, 23, draughtsman, Manchester; Roger Atkinson, 20, analytical chemist, Crewe; Joseph Amscow, 22, chemist, Crewe; W. R. Bousfield, 18, student, Cambridge; W. H. Warren, 21, engineer, Wolverton; William Barber, 20, draughtsman, Nottingham; William H. Fowler, 19, engineer, Oldham; Thomas Sugden, 23, mechanic, Oldham; Cyrus Bullock, 22, millwright, Worsley, near Manchester; John Lockie, 20, engineer, Glasgow.

THE following gentlemen have passed in the First Division on the First B.Sc. Examination for 1873, in the University of London :—P. Bedson, E. B. Cumberland, T. F. Harris, S. A. Hill, W. Hudson, J. Viriamu Jones, O. Lodge, J. G. MacGregor, W. R. Parker, T. S. Tait, C. M. Thompson, A. T. Wilkinson, B.A.

THE "Proceedings of the Geologists' Association," for July, is almost wholly occupied with an account of the interesting and instructive excursions of the Association during the summer months of last year. It contains, besides, a paper by Mr. John Paterson, "On a Visit to the Diamond Fields of South Africa," and another by Mr. John Curry, "On Columnar Basalts."

THE "Mineral Statistics of Victoria for 1872," are made up as usual of a host of tabulated details of all kinds, relating to the minerals and mines of that colony. Owing to changes in the law it seems to be more difficult than heretofore to collect accurate statistics as to the quantity of gold raised, many mine-owners being unwilling to furnish returns. According to returns furnished by the Commissioners of Trade and Customs, the quantity of gold exported in 1872 was 1,160,554 oz. 19 dwts, the estimates of the Mining Registers being 1,331,377 oz. 18 dwts.

A SPECIAL Report on Emigration by the American Government has been sent us, containing a great amount of information likely to prove very valuable to intending emigrants, as well as to statisticians. Not only does it contain statistics as to the number, nationalities, &c. of emigrants during the last few years, but much information as to rent of land, staple products, kind of labour in demand, wages to be earned at various trades and occupations, &c.

THE additions to the Zoological Society's Gardens during the past week include a Silvery Gibbon (*Hylobates leuciscus*) from Java, two Slow Loris (*Nycticebus tardigradus*) and a Binturong (*Arctictis binturong*) from Malacca, a Tiger (*Felis tigris*) from India, presented by Sir Harry Ord, C.B.; a Malay Bear (*Ursus malayanus*) from Borneo, presented by Mr. A. C. Crookshank; a common Marmoset (*Hapale jacchus*) and a Black-eared Marmoset (*H. penicillata*) from Brazil, presented by Mr. J. Stanley; a Cornish Chough (*Fregilus graculus*), presented by Mr. G. Holford; a Gazelle (*Gazella dorcas*) from Muscat, presented by Major C. B. E. Smith; two Blue-headed Pigeons (*Starnaenas cyanocephala*) from Cuba, a White-headed Saki (*Pithecia leucocephala*) from Demerara, and a Hawk-headed Parrot (*Deroptyus accipitrinus*) from Brazil, deposited.

SCIENTIFIC SERIALS

THE *Zoologist* for this month commences with an interesting paper by Mr. T. H. Potts, who is paying so much attention to the birds of New Zealand, on the habits of the Night Parrot of that country (*Stringops habroptilus*). One of its favourite foods is the younger part of the fern *Asplenium bulbiferum*, called Piki-piki, which, being only partly digestible, forms large pellets of excreta on the floor of their tunnel homes. All those who have kept a bird of this species as a pet, agree in testifying to its intelligence and companionableness.—Mr. Cecil Smith, among his ornithological notes from Somersetshire, records experiments, suggested by Prof. Newton, with a view of ascertaining how far birds in general, and especially some of the foster-parents of the cuckoo, have any objection to eggs of a different colour being placed in their nest. In nearly every case the exchange was perfectly successful.—Mr. Gatcombe had an opportunity of examining a Night Heron obtained near Ivybridge, in Devon; he also records other ornithological notes.—A specimen of *Scyllarus arctus* is mentioned by Mr J. S. Bowerbank, as having been obtained by him at St. Leonard's (it was five inches long), as well as an Angel Fish.—Mr. A. G. Butler finds, as one of the effects of the Wild Birds Protection Act, that farmers employ boys to collect and break up all the eggs on their grounds, as they are now deprived of the satisfaction of destroying the birds.

SOCIETIES AND ACADEMIES

LEEDS

Naturalist's Field Club and Scientific Association, Aug. 5.—Mr. Louis C. Miall read a paper on "The Permian Rocks of the Neighbourhood of Leeds." He first described the base of the Permian System. The carboniferous rocks having been disturbed, thrown into anticlinals and faulted, were greatly denuded, and the Permian rocks were then deposited upon the new surface thus produced. The conditions of deposit of the magnesian limestone were then considered. The abundance of mineral salts, exclusive of carbonate of lime, the scantiness of animal life and the dwarfed state of the mollusca, all point to deposition in an inland sea or confined basin similar to the Caspian, Dead Sea, or Great Salt Lake of the present day. In parts of he Triassic period the previous marine surface appears to have become, in part at least, terrestrial or fresh water. At a much later period the Permian rocks, with others of subsequent formation, were denuded extensively, and reduced to the state in which they now occur. The Permian series of the neighbourhood of Leeds were then specially referred to. The Lower New Red Sandstone of South Yorkshire (the Pomfret Rock of Smith) does not appear to be present, at all events in a conspicuous state, in this district. The so-called Lower New Red Sandstone of Plumpton is undoubtedly of carboniferous age. The Upper and Lower Magnesian Limestone are well displayed. Various sections of these rocks at Rigton, East Keswick, Collingham, Whin Moor, and Knaresborough, were described in the paper. Remarks on the colour of the soil produced by underlying Permian rocks on the few fossils which have occurred at Garforth and Cold Hill, near Sherburn, and on the superficial drift, concluded the paper.

VIENNA

Imperial Academy of Sciences, April 24.—Dr. Wiesner presented a work on the influence of temperature on the development of *Penicillium glaucum*. Germination of spores takes place between 1·5° and 43° C.; development of mycelia between 2·5° and 40°; and formation of spores between 3° and 40°. These processes attain maxima of rapidity, the first and third at 22°, the second at 26°.—Dr. Hause gave a paper on the decrease of heat with the height in Asiatic monsoon countries. The decrease is less on the windy side than on the lee. The yearly average decrease is not less in the tropics than in central Europe.

May 8.—Dr. Thin presented a memoir on the structure of touch bodies.

May 15.—Dr. Boué read a paper on petrified bodies which have been forced from their place of deposition; and another on

the formation of the dolomitic Alpine Breccias, as compared with some tertiary mountains in Lower Austria, which resemble them, but are quite distinct in origin.

May 23.—A communication from Prof. Horsford, of Cambridge, U S., treated of the reduction of carbonic acid to carbonic oxide through phosphate of iron.—MM. Hlasiwetz and Habermann concluded their account of researches on protein-stuffs. They find the decomposition-products of casein to be, exclusively, these: glutamic acid, aspartic acid, leucin, tyrosin, and ammonia.—Dr. Heitzmann gave a paper on the relation between protoplasm and ground substance in animal bodies.

June 13.—Dr. Basch presented a note on the retardation of intestinal motion through the nervus splanchnicus.

June 19.—M. Fritsch presented the third part of his normal flower-calendar for Austro-Hungary.—Prof. Maley described researches made along with Dr. Donath on the chemistry of bones. One chief object was to ascertain whether the substance of bones is a combination of calcic phosphate with the lime-furnishing mass, in chemical sense, or whether it is not rather an intimate mechanical mixture of the two constituents. They adopt the latter view.—Prof. Töpler described two applications of the principle of air friction to measuring instruments. A suspended magnet has, connected with it below, and in the same plane, a vertical plate, moving in a closed case, the vertical section of which it nearly fills. By inserting cross walls in the case, the motion of magnet and plate may be deadened by air friction; and that in proportion as the cross plates are pushed far in or not. The other application is for levelling purposes. The observer looks through a telescope at a little square mirror suspended by two threads in a glass case scarcely larger than it. The mirror moves as if in a viscous liquid.—Prof. Suess presented a memoir on the earthquakes of Lower Austria. Two lines of direction are distinguished.—Dr. Holetschek discussed the path of the first comet of 1871.—Dr. Heitzmann described experiments in which he had fed carnivorous animals with lactic acid, and also injected it subcutaneously; the result being arthritis and osteomalacia.

June 26.—Dr. Heitzmann read a paper on the life phases of protoplasm.

July 10.—M. Simony gave the principal results of a large theoretical work occupying him, in which a new molecular theory will be developed, requiring only one matter and one principle of force.—Dr. Böhm gave a note on the germination of seeds in pure oxygen gas. In such gas, of ordinary density, seeds did not get beyond the first stages; but, curiously, if the gas was diluted with $\frac{4}{5}$ of its volume of hydrogen, or rarified to a pressure of 150 mm. they germinated as in air.—Dr. Heitzmann read a paper on the development of periosteum, bone, and cartilage.

July 17.—Dr. Böhm presented a note on the influence of carbonic acid on the verdure and growth of plants. In an atmosphere containing only 2 per cent. CO_2 the formation of chlorophyll was retarded; while 20 per cent. suppressed it entirely in most cases. The gas was also found prejudicial, in various degrees to the germination of seeds.—Dr. Sigmund Mayer described some experiments on direct electrical stimulation of the heart in mammalia.—Prof. Suess gave a paper on the formation of mountains in central Europe, and Dr. Heitzmann one on inflammation of periosteum, bone, and cartilage.

GÖTTINGEN

Royal Society of Sciences, June 14.—M. Waitz read a note on some lost Mayence Annals.—M. Benfey presented a philological paper on the suffixes *anti*, *âti*, and *ianti iâti*, in Sanscrit, Latin, and Greek; also a notice of some Mongolian and Cingalese legendary fragments; and sketched the design of a treatise on "eye-speech," pantomime, gestures, and modulations of the voice, phenomena which he urges travellers to make careful note of, and grammarians to study more than previously, as throwing light on the development of speech and languages.—M. Quincke described a new method of observing circle divisions in telescopic work.—Dr. Voss communicated mathematical notes on the simple transformation of plane curves, and the geometry of surfaces.—Dr. von Brunn described certain smooth muscular fibres found in the suprarenal bodies, accompanying the larger veins, and forming cylindrical or flat bundles.—M. Enneper presented a second note on orthogonal surfaces.—M. Bjerknes made some historical observations on Dirichlet's problem of a ball at rest in an agitated, unelastic, infinite liquid, and generalised some results previously obtained on the subject.—M. Klinkerfues made some remarks on the method of determining parallax by radiants; the results of this method, for Sirius, agree pretty closely with observation.—M. Lolling contributed a lengthy memoir on the topography of Athens. From local study, and the Greek authors, he seeks to determine the position and nature of the Pnyx, the Bema, the cave of Apollo in the Acropolis, and the Metroon. He is now prosecuting these inquiries further.

July 5.—M. Benfey made some remarks on the dual nominative "âsmritadhrû" occurring in the Rigveda.—Fr. Wieseler gave a description of certain valuable specimens of early Grecian sculpture and other antiquities obtained in the East.—Dr. Riecke discussed Weber's fundamental law of reciprocal electric action in its application to the unitarian hypothesis, instead of the dualistic, which Weber adopted; and points out some differences these hypotheses involve in their results.—Dr. Voss read a paper on the geometry of Plücker's line forms.—Dr. von Brunn communicated a short note on ossification of cartilage.

PARIS

Academy of Sciences, Aug. 11.—M. de Quatrefages, president, in the chair.—The following papers were read:—A reply to M. Tacchini's new objections, by M. Faye. The author answered the observations and objections lately published by that observer, of whom he said that "the facts which he cites are in contradiction with the theories which he attributes to me, but not with those which I have really published."—On the Cyanides, by M. Berthelot.—On the re-solution of precipitates, by M. Berthelot.—On the palms of New Caledonia, by M. Ad. Brongniart.—On the carpellary theory applied to the *Ranunculaceæ*, by M. Trécul.—M. Elie de Beaumont furnished some further descriptive matter on the detailed geological map of France.—M. A. Ledieu read the fifth portion of his paper on thermo-dynamics.—On the movements of the tide on the coasts of France, change in the time of high water at Havre since the embankment of the Seine, by M. L. Gaussin.—On the passage of gases through colloidal vegetable membranes, by M. A. Barthélemy.—Note on the methods employed for the analysis of the natural phosphates employed in agriculture, by M. C. Mène. The author strongly advocated the use of the bismuth process, which, he says, never admits of a greater error than 0·25 per cent.—On a cave of the period of the reindeer, at Lortet, Hautes-Pyrénées, by M. E. Piette. The author announced the discovery beneath a deep layer of stalagmite, which covered reindeer remains, of a quantity of prehistoric human relics, and upwards of 500 cubic metres of ashes. The human relics include a drawing, on rein-deer horn, of a heath-cock.—Analytical solution of curve traces of several centres by means of Perronet's geometrical process, by M. Revellat.—On fluorene, by M. Barbier. This is the name given to a hydrocarbon exhibiting great fluorescence, and occurring in coal-tar boiling between 300° and 340°.—On the action of platinum and palladium on the hydrocarbons, by M. Coquillion.—On the variations of hæmoglobin in various diseases, by M. Quinquaud.

CONTENTS

ERRATA.—Vol. viii. p. 299, col. 2, at bottom, Equation (6), should read:—

$$2\left(\frac{1}{D_{12}}\right)^{\frac{1}{2}}\left(\frac{1}{w_1}+\frac{1}{w_2}\right)^{\frac{1}{4}} = \left(\frac{\rho_1}{\nu_1}\right)^{\frac{1}{2}}\left(\frac{2}{w_1}\right)^{\frac{1}{4}} + \left(\frac{\rho_2}{\nu_2}\right)^{\frac{1}{2}}\left(\frac{2}{w}\right)^{\frac{1}{4}} \qquad (6)$$

The calculations were not made by means of this equation, either in it right or wrong form, but from the values of δ given in Table I.—J. CLERK MAXWELL.

P. 300, 1st col. equation (7) should be $l = \frac{1}{\sqrt{2\pi s^2 N}}$; &c.

P. 309, transfer top line of col. 1 to top line of col. 2, p. 308.

THURSDAY, AUGUST 28, 1873

THE REPORT OF THE SCIENCE COMMISSION ON THE OLD UNIVERSITIES

II.

IN relation to the Colleges, the attention of the Commissioners has been principally directed to the following points:—1. The Scholarships. 2. The Fellowships. 3. The Organisation of the Instruction given in the Colleges in relation to the Instruction given in the Universities. 4. Contributions from the Colleges to a fund for University purposes.

After giving a list of the Scholarships filled up in Oxford from January to December 1872, it is remarked that "it is evident upon a comparison of the numbers contained in this list that the Scholarships offered for Natural Science are but a small fraction of the whole number. The state of the case appears to be that the Colleges do not offer Scholarships for Natural Science because they fear they would not get good candidates from the schools; and the schools do not teach Natural Science because they are afraid of injuring the prospects of their pupils by diminishing their chances of obtaining a Scholarship. It cannot be doubted that the effect upon the schools of this unequal distribution of rewards has been, and is, very discouraging to scientific study; and that it has exerted a most unfavourable influence upon the number of Natural Science students."

Without being prepared to concur in this estimate of the relative value of the two objects, we are nevertheless of opinion that it is of great importance, with the view of promoting the study of Natural Science in the first grade schools throughout the country, that there should be an immediate, and ultimately a large, increase in the number of Scholarships offered for this subject by the Colleges.

The part of the report which deals with the Fellowships is of great importance.

After quoting from the evidence of the Chancellor of the University of Oxford and others, evidence to the effect that the present application of the revenues to Fellowships is exceedingly unsatisfactory, the report proceeds:—

"Whilst giving every weight to the considerations urged by Prof. Jowett, and admitting to the fullest extent the great stimulus which the higher education has received at Oxford from the system of election to Fellowships by open competition, we are nevertheless satisfied by the evidence laid before us that an unduly large proportion of the revenues of the Colleges is expended in sinecure Fellowships; and we have reason to believe that this opinion is shared by a large and increasing number of the resident members of both Universities. . . .

"It is doubtless advantageous to the country at large, as has been urged by some of our witnesses, that young men of ability, who choose to enter into one of the great professions, should be supported, or nearly so, in the early years of their professional career, and thereby be enabled to apply themselves at once to the higher studies of their profession, instead of wasting their energies in drudgery of some kind, for the mere purpose of obtaining a temporary livelihood. But this end may be secured by means of Fellowships tenable only for a limited period. It has been urged that the feeling of security given by the system of unlimited tenure greatly enhances the value of a Fellowship. No doubt it is a very comfortable thing for a young man to feel that, come what may, he is secure of an income so long as he chooses to remain single. But we can see no adequate reason why he should be thus comforted at the expense of the College, when he has preferred the more attractive prospect of a professional career in the outer world to the work of the College. . . .

"We are therefore decidedly of opinion that the Fellowships awarded as prizes are excessive in number if not in value, and that the system ought to be remodelled. We are further of opinion that in any such remodelling a considerable proportion of the Fellowships should be suppressed or consolidated for the purposes of contributing to the general fund of the University and of endowing, within the Colleges and the University, new institutions, new offices, in aid of education or research. But it must be remembered that, as Prof. Jowett has stated, the property of the Colleges at Oxford, in some instances at least is greatly increasing, so that quite independently of the suppression of Fellowships there will in all probability be considerable sums available for these purposes. In any case, therefore, we are prepared to admit that a great part of the Fellowships ought to be retained as Fellowships, and the problem that has to be solved is how to employ those which are so retained in the most useful manner possible.

"The following are the chief purposes to which, in our judgment, the Fellowships should be applied:—

"In the first place, a certain but not a very large proportion of the Fellowships will be always required, as at present, for the payment of the persons entrusted with the management of the College estates, and with the government and administration of the Colleges themselves.

"Secondly, a large number of the Fellowships is at present employed, and probably a still larger number ought hereafter to be employed, in connection with the instruction given in the Colleges.

"Thirdly, a smaller, but still a considerable number of Fellowships ought to be employed as Terminable Prize Fellowships.

"Fourthly, a certain number of Fellowships ought, as we have already said, to be united with Professorships in the University; the University professor becoming *ex officio* a Fellow of the College and a member of its governing body.

"Lastly, it is, in our opinion, most important that a certain number of Fellowships should be appropriated to the direct promotion of learning and research in various directions. It has been objected to this proposal that the Fellowship system, as hitherto administered, has not shown any great tendency to encourage original research, either in the field of learning or in that of Science; that, when an office is created simply and solely with the view of giving a man leisure and opportunity for original research, there is always the appearance, to say the least, of creating a sinecure; and that it is impossible, as Prof. Jowett has said, to get a man for money who can make a discovery. But, though you cannot get a man for money

to make a discovery, you may enable a man who has shown a special capacity for research to exert his powers; and we are of opinion that, unless an effort is made to do this, one of the great purposes for which learned bodies, such as the Colleges, exist, may run the risk of being wholly lost sight of. Scientific discoveries rarely bring any direct profit to their authors, nor is it desirable that original investigation should be undertaken with a view to immediate pecuniary results. 'Research,' as Lord Salisbury has observed, is 'unremunerative; it is highly desirable for the community that it be pursued, and, therefore, the community must be content that funds should be set aside to be given, without any immediate and calculable return in work, to those by whom the research is to be pursued.'

"It may be that properly qualified candidates for such scientific offices would not at first be numerous, but we believe that eventually a considerable number of Fellowships might be advantageously devoted to the encouragement of original research.

"We think that such Fellowships as might be expressly destined for the advancement of Science and Learning should only be conferred on men who by their successful labours have already given proof of their earnest desire, and of their ability, to promote knowledge; and we believe that appointments, made with a due regard to this principle, would be abundantly justified by results. A man who has once acquired the habit of original scientific work, is very unlikely ever to lose it, excepting through a total failure of his health and strength; and even if it occasionally happened that a Fellowship awarded on the grounds of merit, as shown in original research, should only contribute to the comfort of the declining years of an eminent man of science, there are many persons who would feel that it could not have been better expended in any other way.

"We should not wish to attach any educational duties properly so called to a Fellowship awarded with a view of encouraging original research in Science. But for many reasons we should think it desirable that the holder of such a Fellowship should be expected to give an account, from time to time, in the form of public discourses, of the most recent researches in his own department of Science."

The last section of the Report dealing with the duty of the Universities and Colleges with regard to the advancement of Science is so important that we give it at length:—

"*Research a primary Duty of the Universities*

"On no point are the witnesses whom we have examined more united than they are in the expression of the feeling that it is a primary duty of the Universities to assist in the Advancement of Learning and Science, and not to be content with the position of merely educational bodies. We entirely concur with the impression thus conveyed to us by the evidence, and we are of opinion that the subject is one to which it is impossible to call attention too strongly. We think that if the Universities should fail to recognise the duty of promoting original research, they would be in danger of ceasing to be centres of intellectual activity, and a means of advancing Science would be lost sight of which, in this country, would not easily be supplied in any other way. There is no doubt that at the present time there is a very strong feeling in the country in favour of the wide diffusion of education, and of the improvement of all arrangements and appliances which tend to promote it, from the simplest forms of primary instruction up to the most advanced teaching that can be given in an University. But there is some reason to believe that the preservation and increase of knowledge are objects which are not as generally appreciated by the public, and of which the importance is not so widely felt as it should be. On this point we would direct especial attention to the remarks of Sir Benjamin Brodie: 'For education we construct an elaborate and costly machinery, and are willing, for this end, to make sacrifices: but, on the other hand, the far more difficult task of extending knowledge is left to the care of individuals, to be accomplished as it may; and yet it is this alone which renders education itself possible. I really am inclined to think that in former days a more real and earnest desire must have existed to preserve knowledge as a valuable national commodity for its own sake than exists now; and the reason that I say this is, that we have existing in the Universities of Oxford and Cambridge records of another condition of things with regard to knowledge than that which exists at present. In the first place we have extensive libraries which could only have been founded and preserved for the sake of the preservation of knowledge itself; and in the next place the collegiate foundations in the Universities were originally and fundamentally, although not absolutely and entirely, destined for the same objects. . . . This object is certainly not less important in modern than in ancient society. I presume that in the middle ages knowledge would altogether have perished if it had not been for such foundations, and it appears that now from other causes the pursuit of knowledge and of general scientific investigation is subject to very real dangers, though of another kind to those which then prevailed, and which make it very desirable for us to preserve any institutions through which scientific discovery and the investigation of truth may be promoted. . The dangers to which I refer are dangers which arise partly even from the growing perception of the practical importance of knowledge, which causes a very great draught indeed to be made upon the scientific intelligence of the country. In the first place, almost every scientific man is caught up instantly for educational purposes, for the object of teaching alone; and, in the next place, a very great draught indeed is made upon Science for economical purposes; I mean for purposes connected with practical life. In sanitary matters we have numerous examples of the vast amount of work done by scientific men for public and practical objects. So that the supply of scientific men is not equal to the demand for those objects alone. Manufactures offer another great field of scientific employment, and it is to be observed that these are the only ways through which an income can be obtained, the pursuit of scientific truth being an absolutely unremunerative occupation.'

"We believe that the dangers referred to in these remarks are real; and their existence induces us to lay down, as emphatically as possible, the position that the promotion of original work in Science should be regarded as one of the main functions of the Universities, and should be specially incumbent upon the holders of those fellowships which, as we have already recommended,

should be awarded with a view to encouraging original research. As regards the professors, we have already insisted on the importance of so arranging their duties as to give them abundant leisure, and, what is no less indispensable, abundant opportunities for original investigation, by providing the external appliances necessary for it. We think that the great national interests connected with the advancement of Science form one, although only one, of the grounds upon which the endowment of professorial offices is defensible, and regard it as a great advantage that an opportunity is afforded by the peculiar circumstances of the Universities of giving encouragement and maintenance to a class of persons who are competent to advance Science, and who are willing to make its advancement the principal business of their lives.

"We have already stated, but we would repeat it here, that we would on no account have offices founded within the Universities without special duties attached to them. It is an absolute advantage, if not in all, at least in many cases, to a man who is engaged in some abstract part of Science, to be compelled to produce, in the form of public discourses, the results of his labours; and it can be no disadvantage to him, under any circumstances, to be obliged to devote some moderate part of his time to showing, if it were only by the example of his own work, to younger men, how scientific studies should be carried on with the view of promoting human knowledge. We believe that in all ordinary cases a certain amount of educational work is of advantage to the scientific worker, and we also believe that for the promotion of the highest scientific education it is very desirable to bring the original worker into direct personal contact with the student.

"We have also already spoken of the propriety of awarding Fellowships in certain instances, not, as at present, by an examination test, but for services rendered to Science in Original Research. Although we should wish, as we have already said, to see this done from time to time (as it has already been done at Cambridge) in the case of persons who have already made themselves eminent in Science, and whose accepting the Fellowship is rather to confer an honour upon the office than to receive one from it, we also think that a wider application should be given to this principle; and, that whenever a Fellowship in Natural Science is offered for competition among the younger Graduates of the University, such evidence as any candidate can offer of his aptitude to become an useful worker in Science, should always be taken into account in the award. Nothing, we believe, would tend to give the students at the Universities so just an idea of what Science is, or of what the objects are which those who pursue it should have in view, as the adoption of the principle by the Universities and the Colleges, that the highest honours and rewards in Natural Science are to be conferred upon men who can offer some evidence that their names are likely afterwards to find a place on the list of those who have added to human knowledge.

"The proposals to which we attach the most importance with a view to the encouragement of Original Research at the Universities are the two to which we have just referred: (1) the establishment of a complete Scientific Professoriate; (2) the appropriation, under certain conditions, of Fellowships to the maintenance of persons engaged in Original Research. But, in addition to these main proposals, other suggestions are contained in the evidence before us, to which we would call especial attention: (1) that Laboratories should be founded expressly intended for Research, and for the Training of Advanced Students in the methods of research; (2) that Scientific Museums and Collections should be maintained to an extent beyond what is required for purely educational purposes; (3) that a Doctorate in Science should be instituted.

"*Proposed Laboratories for Research*

"It is one of the disadvantages of an University course that a young man, up to the time of taking his degree, is straining every nerve in order to master a certain amount of knowledge in which he has to pass an examination; and however improving this process may be to him in certain respects, the impression is widely entertained that it is not caculated to develope the originality of his mind, or those peculiar qualities which fit a man to become a discoverer in Science. As it is indispensably necessary that the student should be well grounded in his work, and should have a thorough comprehension of the methods and principles of his branch of Science, before he attempts to add to it, it is not easy to see how this disadvantage could be remedied during his undergraduate course; but as soon as his examinations are passed, it is surely time that he should be led to regard his studies from another point of view, and to give them a different direction. He should then be placed in a laboratory devoted to original research, and under the immediate care of persons who are principally engaged in work of that nature.

"On this point we would again refer to the evidence of Sir Benjamin Brodie: 'I should like (speaking of my own department and departments which are cognate with it, and I have no doubt that the same remark would also apply to Physiology and to other subjects) to see those professors have under their control laboratories suited for scientific research and investigation, in which they should take a certain limited number of students who would work, partly as their pupils and partly as their assistants, for those ends. And I should myself say that this is an educational function of the most important character possible, because you would here really carry scientific education to its end. If you do not do this you stop short of the most important part of all in scientific education. Now the real perfection of Science is shown only in scientific inquiry—the perfection of Science not only in its general results, but the perfection of Science as an instrument for education; and if you leave out in the University system any provision for scientific research, you are leaving out the most important feature of the subject. Those pupils would be persons who would ultimately pursue the science as their main business in life, and become in their turn the teachers and the professors of the subject. I am not giving a mere chimera or dream, but this is already, though not exactly in the way that I am suggesting, carried out to a great extent in Germany.'

"No less important, as giving one view of this question, is the evidence which we have received from Dr. Frankland, who says, 'In my opinion the cause of this slow

progress of original research (in England) depends, in the first place, upon the want of suitable buildings for conducting the necessary experiments connected with research; secondly upon the want of funds to defray the expenses of those inquiries, these expenses being sometimes very considerable; but, thirdly and chiefly, I believe that the cause lies in the entire non-recognition of original research by any of our Universities. Even the University of London, which has been foremost in advancing instruction in experimental Science, gives its highest degree in Science without requiring any proof that the candidate possesses the faculty of original research, or is competent to extend the boundaries of the science in which he graduates. I consider that this circumstance is the one which chiefly affects the progress of research in this country, because if we inquire into the origin of those numerous Memoirs upon original investigations that come from Germany, we find that a considerable proportion of them are investigations made by men who are going in for their Science degrees, and who are compelled, in the first instance, to make those investigations, and they attain by that means the faculty and liking for original research, and frequently follow it out afterwards; so that a considerable proportion of the papers themselves are contributed in the first place by those men going in for degrees, and a considerable proportion of the remainder are obtained, I believe, through the influence of this previous training in research upon the men who have taken the degrees. Further, the entire ignoring of research in the giving of degrees in this country diverts also, or has a tendency to divert, the attention of the professors and teachers in this country from original research. They have not to take it into their consideration in the training of their students; they have not to devise, as is the case in Germany, suitable subjects for research to be pursued by their students; and thus their attention is, as it were, taken away entirely from this highest field of Science. And, indeed, if they themselves devote some of their time to original research, it almost appears to them to be a neglect of their class duties because their class duties do not require it. Their students are to be trained for subjects which are foreign to original research; they are to be trained chiefly in subjects that are to be taught by lectures, and by what I should call "descriptive," as distinguished from "experimental" or "practical" teaching; and, consequently, I think that in both ways—both by not bringing students into contact with original experimental work, and by diverting the attention of the teachers and professors in this country from such work, great damage is done to the progress of investigation in Great Britain by the attitude of our Universities.'

"Sir William Thomson has gone even further, and has expressed an opinion that the systems of examination in the Universities, as at present arranged, so far from doing anything to encourage the spirit of scientific research, have an exactly opposite tendency. 'That, to some degree, competitive examinations produce an elementary smattering of Science I have no doubt whatever, but I cannot see that they produce much beneficial influence; and in the higher parts especially, they have, I fear, a very fatally injurious tendency in obstructing the progress of Science.'

"The kind of assistance which we should desire to see given in the English Universities to young men who have completed their university course, and who propose to adopt a scientific career, has been from time to time afforded at various institutions in the United Kingdom, among which we may particularly mention the Laboratory of the University of Glasgow, under the direction of Sir W. Thomson. The plan has been adopted in some of the German Universities, and even in the great Polytechnic Schools of that country. In France it has recently been organised on a most complete and extensive scale. The École Pratique des Hautes Études is a Government Institution of which the object is to encourage young men to devote themselves to scientific research, and to give them opportunities of learning its methods. The course pursued by this institution is to take young men who have completed their preliminary scientific studies, and, allowing them an annual stipend to defray the expenses of their maintenance, to place them under the care of competent professors, who give them assistance and advice in their first researches, and to whom they afterwards become useful. This plan appears to us so excellent in itself, and at the same time so academic in its general character, that we desire to recommend it for adoption at Oxford and Cambridge. To insure due attention to both classes of students, it would be proper that the laboratories intended for training in the methods of research should be distinct from those in which more elementary instruction is given.

"We are also of opinion that arrangements should be made in some of the public buildings of the Universities, for giving opportunities to members of the Universities, no longer *in statu pupillari*, of prosecuting researches; although we should regard it of primary importance that these arrangements should be such as not to interfere with the teaching duties, or with the scientific work, of the professors. We agree with Dr. Frankland that one 'cause of the slow progress of original research' in England is 'the want of suitable buildings for conducting the necessary experiments connected with research;' and we think that the Universities might, with great propriety, supply this want, so far as their own members are concerned. We also think that collections of apparatus should be formed, which would be available for the use of such independent workers in Science. There are some obvious difficulties involved in this plan, which has been strongly recommended by some of our witnesses, but which, so far as we are aware, has not been anywhere practically tried. We should, however, look with confidence to such a body as the proposed 'University Council of Science' to frame suitable regulations as to the fitness of the persons admitted to the privilege of working in an University laboratory, and as to the securities to be taken for proper care in the use of valuable instruments. We are disposed to think that, under the special circumstances of the Universities, they would do more to promote original work by offering facilities of the kind which we have described than by making grants of money similar to those which are made in aid of special researches by the Government Grant Committee of the Royal Society. The plan would have the collateral advantage of rendering residence at the Universities attractive to scientific men.

"Proposed Special Scientific Collections

"Although we think it desirable that Scientific Museums and Collections should be maintained in the Universities to an extent which would render them available for original research, as well as for the purposes of education, we do not attach the same importance to this point as to the preceding, because museums and collections have been formed and will be formed in other places than in Universities, whereas laboratories adapted for the instruction of students in the methods of scientific investigation are not likely to be founded except in connection with educational institutions; and although it is a disadvantage to a scientific man not to have all the collections that he desires immediately at his hand, yet, considering the proximity of the Universities to London, it cannot be said that this disadvantage amounts to more than an inconvenience.

"We also are of opinion that it is very desirable that such more extensive collections as may be formed in the Universities should, as far as possible, be kept separate from the more limited collections intended for educational purposes. A Museum may be very easily made too large for these purposes, and instead of giving the student clearer ideas, may serve to confuse him.

"Proposed Doctorate in Science

"We have already referred to the possibility of instituting Higher Degrees, to be conferred upon students, not in accordance with the results of an examination, but upon their giving proof of capacity for original research. The evidence of Dr. Frankland and of Sir William Thomson, which we have already quoted, and to which we might add that of the late Prof. Rankine, appears to us conclusive upon the point that there is a real danger in the examination system; and in our opinion this danger might be guarded against by instituting a higher degree in Science, the obtaining of which should be regarded as a great honour, and which should not be awarded except with reference to original work. The plan of requiring from a candidate for the Doctorate in Science a dissertation embodying an account of some original research of his own is strongly approved by such competent witnesses as Dr. Siemens, Dr. Carpenter, and Prof. Frankland. This plan has been adopted in several of the German Universities, and has now become the established rule in France."

METEOROLOGICAL CONFERENCE AT LEIPSIG DURING AUGUST 1872*

OF the Congresses which have recently been held, none were more urgently called for than an International Congress of Meteorologists. Doubtless even under the diverse systems of observation which have been in use at national observatories and among meteorologists of different countries, large and valuable contributions have been made to Climatology and other departments of Meteorology. We need only refer to the various charts which have been published, showing the geographical distribution of atmospheric and oceanic temperature, of atmospheric pressure, of humidity, of prevailing winds, and of rainfall, and to the enormous amount of materials now being amassed, illustrative of the nature and course of storms, to show the important results which have been obtained. It must, however, be confessed that, as respects nearly the whole of this information, it can be regarded as valuable only in the sense of its being sufficiently approximate so as to meet the requirements of some of the more pressing practical questions of the science, and not because it is precise.

It is when we attempt inquiries into such questions as the diurnal and annual march of the different meteorological elements, and the relations of these elements *inter se*, and of weather on a large scale, that the general unsatisfactoriness of the systems by which observations are made in different countries comes to be forcibly felt, owing to their want of precision and uniformity. The want of uniformity is most conspicuous as respects temperature, humidity, and wind—or just those fundamental facts which must be scientifically observed and discussed before we can hope to solve the problem of weather changes.

In order to bring about a greater uniformity of procedure in different countries, it was proposed to hold a Meteorological Congress at Vienna in 1874. In June last, Bruhns of Leipsig, Wild of St. Petersburg, and Jelinek of Vienna, issued an invitation to meteorologists to attend a preliminary conference to be held at Leipsig in August, for the purpose of preparing the programme for the Vienna Congress, to instigate preparatory experiments on some of the more important questions, and thereby render it possible for the Congress to arrive at immediate conclusions on many points. The Conference was thus only consultative. Accompanying the invitation were a series of twenty-six questions, which it was proposed to submit to the consideration of the Conference.

Upwards of fifty persons attended the meetings of the Conference, which lasted three days. The opinions of the different speakers on the points raised by the 26 questions are detailed in the pamphlet before us, which contains also the written opinions of 14 meteorologists who were unable to be present, including the well-known names of Dove, Rabenson, Mohn, Mühry, and Wolf, as well as the results of the deliberations of the French meteorologists at Bordeaux in September. The subjects treated of may be conveniently classed under the heads of instruments, their position, the methods of discussing, publishing, and utilising the observations.

Barometers.—To those who have attempted to discuss weather, it is well known that nothing exact or satisfactory need be looked for in the result, unless observations from numerous barometers well distributed be available. It is thus desirable that barometers be procurable at a moderate price for stations of the second order. Are Board of Trade barometers—barometers fitted with a float—or aneroids, suited for such stations; or is there any other cheap form of barometer that would serve the purpose? After a lengthened discussion it was referred to Dr. Hann of Vienna to prepare a report for the Vienna Congress. The most diverse opinions were expressed regarding the aneroid, arising probably from the experience of the different writers and speakers—some aneroids going well for years with no permanent alterations occur-

* Report of the Proceedings of the Meteorological Conference at Leipsig. Protocols and Appendices Translated from the Official Report, Appendix to Vol. vii. of the "Zeitschrift für Meteorologie." Published by the authority of the Meteorological Committee. London, 1873.

ring in their indications ; some going well so long as a small range of pressure is recorded, but undergoing alterations after every great barometrical depression ; some constantly altering in one direction, others in either direction, &c. Since, however, it can be safely affirmed of no aneroid, how good soever it may have proved itself to have been, that it will continue to indicate correctly for even a brief time to come, the Conference came to the sound conclusion that the aneroid should not be used instead of the mercurial barometer, but only as an interpolation instrument, to fill up blank when the mercurial barometer is out of order, or when it cannot be observed on board ships in rough weather.

Maximum and Minimum Thermometers.—Rutherford's minimum spirit thermometer was regarded as satisfactory. On it being pointed out by several members that this thermometer is liable to go out of order by the spirit evaporating and condensing in the upper end of the tube, Ebermeyer, of Aschaffenburg, stated that this objection could be removed if the tube were at its entrance into the bulb inserted nearly up to the inner side of the bulb. We commend this suggestion to opticians ; for if Ebermeyer's experience be confirmed, a source of serious and not infrequent error will be removed. On the other hand the performance of no *maximum thermometer* was considered to be so satisfactory that a uniform construction could be generally recommended ; and the opinion was expressed that it was very desirable that a trustworthy maximum thermometer was devised, not liable for instance to have the mercury disturbed during high winds like Negretti and Zambra's, or the index portion go out of order as Rutherford's or Phillip's.

Instruments for Radiation.—Mr. Symons, who has paid much attention to this question, has been requested to give a report to next Congress on the modes of observation adopted in England for radiation. But it must be confessed that the methods of observation in this important inquiry are still in a very primitive state. Mr. Salt well pointed out that at present the results obtained with different instruments were not comparable with each other, and one hardly knew with the instruments now in use what was really observed.

Hygrometers.—Since the dry and wet bulb hygrometer is not trustworthy at low temperatures and in cases of extreme dryness, and the hair hygrometer fails also at the dew points, and since there is no hygrometer yet devised, at least for regular observations at stations, which gives approximately exact results as to moisture in all cases, it was recommended to make further experiments and collect the experience of meteorologists on the subject. From the favourable opinions expressed by Wild and others of the action of the hair hygrometer, further experiments with this instrument are very desirable, so that it might be made available for more accurate observations on the hygrometry of the air at temperatures below the freezing-point than the dry-and-wet hygrometer admits of. Another desideratum is an extensive series of experiments with Regnault's hygrometer in conjunction with the dry-and-wet bulb hygrometer in dry hot climates such as N.W. India, for the purpose of ascertaining how far the readings of the dry-and-wet bulbs can be used as data from which the dew-point may become known ; and determining the requisite data for the correction and completion of the present hygrometric tables, particularly at points below freezing, and at high temperatures combined with great dryness.

Wind.—Curiously enough, the question of proper instruments for measuring the velocity and force of the winds does not seem to have been under discussion, even though it is one of the most important and pressing questions of the science. Anemometers, both for velocity and pressure, are indispensable to properly equipped observatories. Now it cannot yet be said that the anemometers for velocity give quite correct indications that they are comparable, *inter se*, and that we have a practicable means of ascertaining their errors from time to time.

Equally remarkable was the omission in the discussions, to consider what are the required conditions which anemometrical stations ought to fulfil, so that the instrument shall indicate the true movement of the air over the region where it is placed ; or, if this cannot be accomplished, what observations should be instituted in order to ascertain how far the direction of the wind is deflected by the physical configuration of the surface, and its force diminished (or in rare cases accelerated) as compared with the general movement of the air over the place.

Pressure anemometers at a moderate cost are a great desideratum. Little satisfactory is known of the relation of pressure to velocity.

Rain.—The Committee proposed that a report of all the experience regarding the position, size, height above ground, and time of reading the rain gauge which has been yet gained should be prepared for the Vienna Congress. For the preparation of such a report the great storehouse of facts at hand are those collected by Mr. Symons in the successive parts of his "British Rainfall" and "Meteorological Magazine," which the members of the Congress would do well to consult.

Evapometer.—The present state of the evapometer is one of the least satisfactory of all the meteorological instruments. Considering the importance of the drying property of the air in relation to meteorology generally, but especially as one of the most important constituents of climate, it is to be hoped that some method will be devised by which results, at least roughly comparable to begin with, may be obtained.

The difficult, but vital question of the position of the thermometer does not seem to have been faced by the conference. It is earnestly hoped that the Vienna Congress will not shirk this question, but will seriously discuss it and arrive at some decision, or suggest some steps to be taken, that will ultimately lead to the degree of uniformity which is so imperatively called for. Till this be secured, the expensive systems of horary or continuous registration of temperature carried on at the great observatories of this and other countries, cannot supply the data for the determination of temperature "constants," seeing that they are incomparable with each other, as well as with the observations made at those numerous stations of the secondary order to which we must look for the working out of the great national question of local climates in their bearing on the health, productions, and commerce of the country. The question would be of comparatively easy solution were it possible, in the interests of cosmical inquiries, to ignore the past. But it is essential in the

case of the older observatories to adhere to the same system of observing hitherto in use; until at least four or five years' observations have been made simultaneously with a second set of instruments placed in uniformity with those of other observatories.

The question of the practicability and utility of Weather and Storm Signals in Europe was considered, and it was remitted to Messrs. Buys Ballot, Scott, and Neumeyer, to collect the opinions of meteorologists on this important question, and draw up a report for the Vienna Congress. As it is understood that the committee have collected a good deal of information, some valuable results may be expected.

In the "Sequel to the Suggestions," Dr. Buys Ballot has suggested for the consideration of the Congress, the establishment, by societies, of stations in regions which are at present a blank. The Smithsonian Institution, the Dutch Meteorological Institute, and, in our country, the Scottish Meteorological Society have, with the means at their disposal, done a good deal in this direction, with results which have aided much in the furtherance of the science. But to fill up the enormous blanks which still disgrace British America, South America, most of Africa, and the Pacific, some concerted action on the part of meteorologists is indispensable. In connection with this proposed development, reference may be made to the scheme in contemplation by the Chinese Government, in carrying out which Mr. Campbell has been sent to this country to request advice from scientific authorities as to the general organisation of the stations, and to procure the necessary instruments, registers, &c. Towards the carrying out of this plan, the Congress will doubtless give Mr. Campbell very hearty support.

THE TYPHOID EPIDEMIC IN LONDON

THE recent outbreak of enteric fever in the West End of London presents many points of remarkable interest and teaches many useful lessons. Typhoid, Enteric, or Pythogenic fever, although a disease about which all our accurate knowledge is quite recent, is a fever about the causes of which we really know a great deal, but which, for all that, seems to appear from time to time in the places where it might be least expected.

About the nature of the poison which produces it we know as yet but little; we know that its habitat is in the refuse matters excreted from human intestines; we know that it is, under certain circumstances, developed in such excretal matters during their decomposition, but it is yet a moot point whether it is from time to time produced *de novo* under suitable conditions, or whether it is always necessary that some of the poison, however small a quantity, be introduced from without to cause such decomposing matters to become infectious. We are accustomed to regard this as the least specific of the diseases of its kind, but each outbreak which is traced to its source gives a rude shock to such ideas. The "filth-born" fever *par excellence*, it ought not, one would think, to need to wait to be introduced to the country places where, year after year for centuries, the shallow wells from which drinking water is obtained are, in effect, the drains of the premises; or to the town houses, in which the only ventilator to the sewer is the waste pipe which opens directly over the surface of the water in the cistern; but yet such is the case so universally, that when we cannot find out how the poison has been introduced, we should acknowledge our inability to do so, and not cut the knot by saying that it has originated on the spot, a conclusion for which, in the present state of our knowledge, we have no real proof whatever. The number of instances in which epidemics have been traced to single imported cases is now so great that, although it does not actually prove that such is always the case, still it should make us hesitate before declaring that the disease has broken out without direct importation in any given place.

The facts relating to the epidemic which still engages general attention in England, are, in order of sequence, and independently of any theory at all, as follows:—

The disease was noticed to be prevalent, in the middle and latter part of July, in certain houses in the parish of Marylebone, and notably in houses inhabited by medical men, houses where every possible precaution was believed to have been taken: it was observed by Dr. Murchison that an undue proportion of the persons attacked obtained their milk from a particular dairy, and on further investigation the conviction grew upon him that this milk was, somehow or other, contaminated with typhoid poison, and was spreading the disease. A difficulty arose, inasmuch as the locality in which the fever cases were was only a small part of the district supplied with milk from the suspected dairy; but Mr. Radcliffe, on examining the mode of distribution of the milk, showed that on the hypothesis that the milk from one of the several farms was contaminated before coming to the dairy, a localised outbreak or several localised outbreaks of fever must have been the result; so that any suspicion which may have existed as to the cause being possibly to be found in the precincts of the dairy in London, vanished at once.

On the other hand it was found that the owner of one of the dairy-farms had died on June 8; that he had been out of sorts since early in May, and sufficiently so for his two medical men to consult with a third on the subject; that the medical men all suspected that he had enteric fever; that this suspicion became stronger when the patient passed a large quantity of blood and putrid matter on June 1, which blood, &c., was ordered to be buried away from the house, as being most probably infectious; that the patient became considerably better towards the end of the first week of June, but that he died suddenly on June 8 while getting out of bed, no medical man being present; and finally that the medical attendant not being sure of the diagnosis of enteric fever, and considering that, anyhow, the man had got over it, certified that he died from heart disease, as he had for years been suffering from the effects of a "fatty heart;" nevertheless he took the precaution to have the body buried as speedily as possible, thinking that it might be infectious.

Taking all the facts together, these two series of events present at any rate a most remarkable coincidence; and when we find that enteric fever is and has for some months been prevalent in the villages near the farm and in daily communication with it, and that a son of the farmer has since had the disease, the conclusion is irresistible that the farmer died of enteric fever, and that he

had it at a time most singularly adapted to account for the outbreak in London.

The description of the farm-yard itself has been given elsewhere; suffice it to say that the well really drained the premises, and there is little doubt but that the poison got into the water, which was so bad that it had long been condemned as unfit to drink.

Hitherto epidemics of typhoid spread by means of milk have been attributed to the admixture of water as an adulteration with it ; in this case no such suspicion arises, the milk was exceptionally rich, and was daily tested with sufficient accuracy to show adulteration with any but a small amount of water ; but the water from the well was conveyed to the dairy pump by a pipe, and was used for washing the dairy utensils, so that it is easy to account for the presence of a small amount in some of the "churns," an amount, however, enough in so favourable a pabulum as milk to infect a very large quantity of it.

The lesson to be drawn is that all dairy-farms must be subject to regular sanitary supervision, especially as to their water supply, that such details of arrangement with regard to the cleansing of the vessels as may seem to offer least chance of the possibility of mischief should be adopted, and that the presence of infectious disease among the *employés* should be noted at once, and the proper precautions, which are now well known, taken.

W. H. CORFIELD

DOLMEN-MOUNDS *v.* FREE-STANDING AND TRIPOD CROMLECHS

MR. W. COPELAND BORLASE, the talented author of "Nænia Cornubiæ," in his communication to NATURE (vol. viii. p. 202), calls attention to the structure of Lanyon Quoit as an undeniable example of a British tripod cromlech or free-standing dolmen, by way of "protest against the *dictum* of Mr. Lukis being extended to our British examples, before a careful scrutiny has been made of every monument of the kind, from one corner of our isles to the other."

To my friend Mr. Borlase I owe my personal acquaintance with the numercus non-historic rude stone monuments in the Land's End district ; and, as he is a life-long resident in the immediate vicinity of these interesting relics, to which I am a mere casual visitor, it is with feelings of great delicacy and diffidence that I now venture to place in a somewhat different aspect the statements and conclusions which he would wish your readers to adopt.

It were strange if Mr. Borlase did not turn out the best authority on early Cornish remains, for within six or seven miles of his residence at Castle Horneck (itself the site of an ancient Cornu-British encampment) there are at least twice as many dolmens as in all the rest of England ; and though there may be perhaps as many in Anglesea, and twice as many in Wales, still West Cornwall has an advantage over both these districts, viz., that in Wales and Anglesea, the country of the Silures, there are no circles but only dolmens ; in Cornwall, as in the Isle of Man, there are both circles and dolmens, the result, as Fergusson tells us, of an Ibero-Aquitanian admixture with Celtic and other (Scandinavian ?) blood in the inhabitants. (*Vide* "Rude Stone Monuments," p. 163.)

Inheriting the tastes and following in the footsteps of his great-grandfather of antiquarian renown, Mr. Borlase has made great use of his opportunities, and is continually adding to, or accumulating store of facts with regard to the ancient history of our country. On the other hand, most antiquarians will probably agree with me in maintaining that the Lukis family may be reckoned some of the best, if not the very best authorities, on the chambered barrows of France and the Channel Islands. Enormous numbers of these structures have been scientifically examined and exhaustively described by the Messrs. Lukis : and the Rev. W. Lukis, in company with Sir Henry Dryden, is now employed in drawing to scale plans and elevations of the Isle of Man remains, and thereby carrying out his share of that scrutiny which Mr. Borlase anxiously demands in his letter.

When such authorities disagree, it would seem almost impertinent to interfere ; but knowing my friend Mr. W. Lukis to be busily engaged in the Isle of Man, and too far off to personally examine the monument in dispute, whilst I was within a three hours' journey of the structure I determined to see the cromlech myself, and having done so, cannot allow Mr. Borlase's letter to remain unchallenged.

In taking up the cudgels for Mr. Fergusson, Mr. Borlase must not be looked upon as an implicit follower of that author, whose work he characterises as "*unreliable*,"* although, with him he is convinced "that the barrows and the cromlechs (if not the circles too) were the sepulchres of the dwellers in the hut circles and the earthworks ; and that these latter were the residences of the Romanised Britons in the earlier centuries of the Christian era ;" for before the appearance of "Rude Stone Monuments," he struck out for himself the formation of "a small class or species of dolmen," viz. the tripod cromlech, or dolmen proper (see "Nænia Cornubiæ," p. 14, *et seq.*), "where, as Col. Forbes Leslie remarks, 'the vertical supporters of the tabular stone are columnar,' and cannot be said to enclose a space."

Before proceeding, it may be as well to remark what Mr. Borlase ignores, viz. that (as may be seen from the title to his paper) the criticism of Mr. Lukis (deserved, if severe) of "Rude Stone Monuments," was based upon the application of the "*Free-standing*" theory, by the author, to the monuments of France, where he *proved* it was inapplicable. He said nothing at Somerset House about English monuments, although I believe it is his intention to say something about them on a future occasion. Mr. Borlase severely attacks Mr. Lukis, as though, in removing the *French* monuments from the supposed "free-standing class, he condemned all persons who held their own views on *British* ones. Mr. Lukis' views are not "hypotheses." He simply declares that the plans of *French* monuments which he produced before the Society of Antiquaries in London teach the proposition he laid down, and that it is the duty of those who are unacquainted with these examples to verify or disprove his statements and descriptions by visiting and inspecting them, and not to try and write him down when they have a very imperfect knowledge of them, or none at all. Previous to taking stock of Mr. Borlase's weighty evidence in support of Lanyon Quoit as originally a dolmen proper, *i.e.* a tripod cromlech, it should be noted what Fergusson states in respect to the West of England dolmens. In "Rude Stone Monuments," p. 163, he says : "*Even a cursory examination of these West Coast dolmens would, I think, be sufficient to prove to any one that the theory that all were originally covered with earthen mounds is utterly untenable.*" Exactly so ! A *cursory* examination (which, if we are to believe Mr. Borlase, it appears that Fergusson never took the trouble to make, at least as regards the Cornish circles)† is very likely to lead the uninitiated hasty observer to suppose as above. What a prolonged investigation will prove I leave the reader to find further on. It is, at all events, unfortunate for this theory that Mr. Borlase can only produce *two*‡

* See Mr. Borlase's letter to the *Antiquary*, July 27, 1872.

† Letter to the *Antiquary*, July 27, 1872.

‡ Mr. Borlase mentions a possible third example, in his "Nænia," p. 26. A fallen cromlech, which may have possibly belonged to the "tripod class," is to be found near Helmen Tor, in the parish of Lanlivery.

examples of the tripod class in all Cornwall, viz. those of Lanyon and Caerwynen, and those are both *modern restorations of dilapidated ruins:* not a single stone of either of these examples is as it originally stood "*in situ.*" I did not see Mr. Borlase's letter to NATURE until the 3rd inst. On the 5th I obtained old Dr. Borlase's quaint volume on the "Antiquities Historical and Monumental of the County of Cornwall" (2nd ed. 1769), from a chapter in which volume Mr. Fergusson borrows his title of "Rude Stone Monuments," and on the following day visited Lanyon Quoit itself, sketched it, and compared the accounts of it on the very spot, and the following is the result of my investigation. I will take Mr. Borlase's statements categorically :—

(1) Lanyon Quoit "always *was*, as it is now, a free-standing dolmen."

(1) I humbly submit that Lanyon Quoit could not possibly have been always as it is now, from the fact of its having fallen, during a violent storm in 1815, whilst a comparison of its plan, as it now is in its restored state, and as it is given by Dr. Borlase, shows that the stones have been moved. The supporters were originally parallel, and are now at different angles to one another.

(2) "A tripod dolmen consisting of three slim pillars supporting on their summits a horizontal stone."

(2) I leave it to my readers to judge from the accompanying representation (from a photograph) of the cromlech whether, from the flat nature of the component stones, the supporters have not more or less the character of slabs rather than that columnar shape necessary for the so-called "Table stone proper:" and whether the *three slim pillars* would not have been more accurately described as *stout stone slabs.* The good Rector of Ludgvan, more than a hundred years ago, more aptly described these Cornish monuments.* "Three or four large flags or thin stones capped with a much larger one, which go by the British name of cromlêhs;" and again, "In several parts of Cornwall we find a large flat stone in a horizontal position (or near it) supported by other flat stones fixed on their edges and fastened in the ground." He never mentions pillars or columnar supports.

Mr. Borlase omits to mention the *fourth* slab (D) which is prostrate to the north (see plate), and the *fifth* and *sixth* flat stones (E and F) (possibly one broken in two) which lie imbedded in the soil at the foot of the south supporter, in which position they were apparently placed by the restorers in 1824 to prop up the upright slab.†

(3) Two drawings of it in its pristine condition by Canon Rogers, 1797, and Dr. Borlase, 1747, "agree in representing the slimness of the pillars, their distance apart, and great height of monument, features which render it not unlike a gigantic three-legged milking-stool."

Dr. Borlase's drawing shows *four* upright slabs, although the fourth does not apparently touch the capstone. I think that the supporters A, B, C, may be identified with those in Dr. Borlase's drawing with tolerable certainty, and D, now prostrate, was the fourth upright : that E and F were once also upright is highly probable.

(4) Then, as now, there was no mound about it. It stood on a low bank of earth and the area had been often disturbed by treasure-seekers."

(4) Dr. Borlase says "this cromlêh stands on a low bank of earth not two feet higher than the adjacent soil, about 20 feet wide and 70 feet long." The cromlech stands as much in as on the long mound which, according to the above measurements, would contain at least 2,000 cubic feet of earth, besides the *many rough stones* "not the natural furniture of the place," which Dr. Borlase also mentions. It bears every appearance of having formed the base of a long barrow.

* Antiquities, pp. 159 and 223.

† The younger Borlase acknowledges that "several of the stones had been broken." "Nænia," p. 18.

(5) "No houses are near it which could have received the stones of a denuded mound."

(5) A good road with rough stone walls on each side of it, which runs within a few yards of the cromlech, would well account for a portion of a denuded mound or cairn whose stones would be well adapted for building the walls and metalling the road.

(6) "It is difficult to see how a kist-vaen or septum of any kind could have been formed beneath the cap-stone. Had a wall of *small* stones been built from pillar to pillar the height of the superincumbent mound must have forced them inwards, a catastrophe which the "dolmen-builders" were always careful to avoid."

(6) Mr. Borlase must have had experience in his researches among the underground bee-hive caves to know how extensively microlithic dry masonry can be so built up as to resist any outside pressure of a superincumbent mound.

(7) "Had *large* stones placed on edge formed the walls of the kist, how is it they are *all* removed, while every other cromlech in the district retains them?"

(7) In "Nænia Cornubiæ," p. 43, Mr. Borlase writes, with regard to Lower Lanyon Cromlech, "Two stones are all that now remain, viz. the covering stone and one of the supporters; the others having been split up and carried away for building."

(8) "My strongest proof is yet to come. The interment was *not in the kist at all.* A grave had received the body six feet under the natural surface of the surrounding soil, and within the area described by the structure. This being the case, of what use could an enclosed kist have been, or why should the cenotaph be covered in at all?"

(8) Dr. Borlase discovered a pit within the area of the kist-vaen of Mulfra Quoit; and Mr. Borlase himself relates in his Nænia "a small pit seems to have been sunk in the centre" of Chywoone cromlech which he acknowledges was buried in a tumulus. This method of interment would therefore seem common to these three structures.

(9) "On the southern side of the structure, and so near it that a mound over the monument must have inevitably covered it up, stands a little circular ring cairn of the ordinary type, in the centre of which I found the remains of an inner ring which, though now rifled, had doubtless contained an interment."

(9) Dr. Borlase mentions with regard to the long low bank above-mentioned "at the south end, has (*sic*) many rough stones, some pitched on end, in no order; yet not the natural furniture of the surface, but designedly put there; though by the remains, it is difficult to say what their original position was."

Should Mr. Borlase's recognition of the confused aggregation of stones as a ring cairn be correct, it is by no means inconsistent with the theory that a mound once enveloped the cromlech and (as Mr. Borlase suggests would be the case) included the ring cairn in its area.

A parallel case occurs at Moustoir Carnac in Brittany, a plan and section of which, after M. Galles, is given in Fergusson's work, p. 358, and which I have personally examined. Here we find a true dolmen, *two* ring cairns, and a kist within one large long tumulus or barrow.

From my own inspection, I agree with the older Borlase, that "nothing is to be absolutely concluded, there having happened so many disturbances," but I have little doubts that whatever it was it formed some part of a structure in connection with and belonging to the cromlech.

Whilst comparing Cornish cromlechs with French dolmens, a comparison should be made between Chywoone cromlech* and Mr. Fergusson's characteristic example at Grandmont† in Bas-Languedoc (woodcut No. 128), with regard to which he says, "The umbrella form is hardly

* Nænia Cornubiæ, p. 55.

† "Rude Stone Monuments," pp. 343, 344. Figured in NATURE, vol. v. p. 387.

such as would ever be used for a chamber in a tumulus, but as a pent-roof is singularly suitable for an open-air monument."

The Chywoone cromlech has a peculiar convex-shaped cap-stone or pent-roof; so much so, that "the Quoit itself, seen from a distance, looks much like a mushroom." Mr. Borlase calls it the most perfect and compact cromlech in Cornwall. On exploration, "it was first of all discovered that the building rested on the solid ground, and not on the surrounding tumulus in which it had been subsequently buried." . . . "The barrow or cairn, which in some places nearly reaches the top of the side stones on the exterior, is thirty-two feet in diameter, and was hedged round by a ring of upright stones." . . . "It was discovered that the interstices between the side stones had been carefully protected by smaller ones placed

FIG. 1.—Restoration of sole remaining chamber of Lanyon Cromlech, showing fallen side slabs. View from the east.

in such a manner as to make it impossible for any of the rubbish of the mound to find its way into the kist."

Mr. Borlase remarks that "the *noscitur a socio* is a principle too lightly regarded by those on whom it forces a conclusion they do not like. In the case of antiquities it is, if judiciously used, extremely valuable." Applying this principle to the two Lanyon cromlechs, is it not just possible that some former owner of the upper cromlech has done what the late owner of the lower one did, viz.,* "remarking that the earth was rich, he thought it might be useful for a compost. Accordingly he sent his servants soon after to carry it off, when, having removed near a hundred cartloads, they observed the supporters of a cromlêh."

After the above it is hardly necessary to allude to the Caerwynen cromlech, which has been re-erected in a

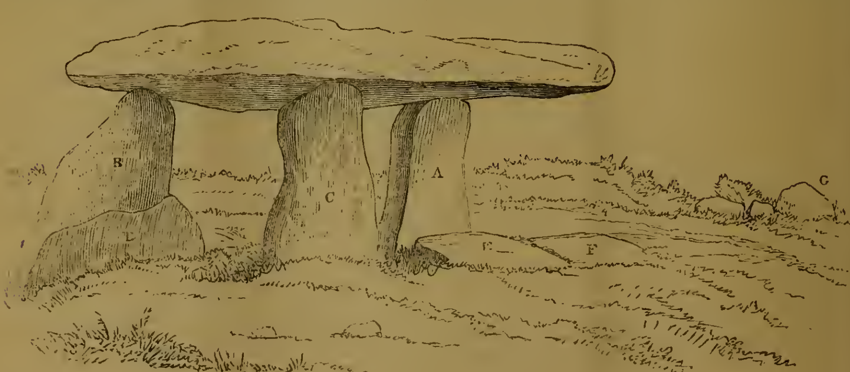

FIG. 2.—Sketch of Lanyon Quoit from the north-west.

gentleman's park, more as an ornamental monument than as an archæological record. It is noticeable that in its immediate vicinity is a heap of stones overgrown with thicket, which evidently had some connection with the structure, which was composed of more than four stones.

In conclusion, it seems to me that the distinction between the dolmens proper and the kist-vaen cromlechs only adds to the difficulties surrounding the subject, and I fear that Mr. Borlase's letter will not tend to strengthen an already weak cause.

NOTES FROM THE "CHALLENGER"

VI.

WE left Bermudas on Thursday, June 12, for the Azores. His Excellency Gen. Lefroy, C.B., F.R.S., Governor of the Island, with his private secretary, Capt. Trench and Capt. Aplin, R.N., Captain Superintendent of the Dockyard, and a party of ladies, came on board in the afternoon, and we bade farewell, with great regret, to the friends from whom we had received such unvaried kindness during our stay. At half-past five we steamed out of the Camber and passed among the reefs to Murray's Anchorage, on the north-east side of the island, where we anchored for the night. Next morning we proceeded through the narrows, and early in the forenoon, having seen the last of the treacherous and beautiful purple shadows in the bright green waters of Bermudas, we set all plain sail and stood on our course to Fayal. In the afternoon we got up steam and sounded, lat. 32° 37′ N., long. 64° 21′ W., in 1,500 fathoms, with the usual grey-white chalky bottom which surrounds the reefs.

Our position, at noon of the 15th, was lat. 33° 41′ N., long. 61° 28′ W., 1,610 miles from Fayal.

On the morning of the 16th we sounded in 2,575 fathoms, the bottom a reddish ooze, containing a large number of foraminifera. The bottom temperature was 1°·5 C. A small, rather heavy trawl, with a beam $11\frac{1}{2}$ feet long, was put over in the morning, but when it was hauled in, about five in the afternoon, it was found that it had not reached the bottom. This was the first case of failure with the trawl. It was probably caused by the drift of the ship being somewhat greater than was supposed. The net contained a specimen of one of the singular and beautiful fishes belonging to the Sternoptychidæ, an aberrant family of the Physostomi, distinguished by having on some part of the body ranges of spots or glands producing a phosphorescent secretion. The surface of the body is, in most of the species, devoid of scales, but, in lieu of them, the surface of the skin is broken up into hexagonal or rectangular areæ, or separated from one another by dark lines, and covered with a brilliant silvery pigment, dashed with various shades of green or steel blue. We have taken, in all, four or five species of these fishes, all in the net, when dredging or trawling, at great depths. I do not think they come from the bottom, however. It seems more probable that they are caught in the net on its passage to the surface, possibly at a depth of two or three hundred fathoms, where there is reason to believe there is a considerable development of a peculiar pelagic fauna.

On Tuesday, the 17th, the trawl was lowered at seven in the morning, and in the forenoon a sounding was taken in 2,850 fathoms.

Several examples of a large and handsome species of the genus *Scalpellum* came up in the trawl, a few still adhering to some singular-looking concretionary masses which they brought up along with them. One of these lumps, to which a large example of the barnacle was attached, was irregular in form, about three centimetres in length, and two in width. The surface was mammellated and finely granulated, and of a dark-brown colour, almost black. A fracture showed a semi-crystalline structure, the same dark-brown material arranged in an obscurely radiating manner from the centre, and mixed with a small quantity of a fragment of greyish-white clayey matter. This nodule was examined by Mr. Buchanan, and found to consist, like the nodules dredged in 2,435 fathoms at Station 16, 700 miles to the east of Sombrero, almost entirely of peroxide of manganese. Some other concretionary lumps were of a grey colour, but all of them contained a certain proportion of pyrolusite, and they seemed to be gradually changing into nodules of pyrolusite by some process of alteration or substitution. This is undoubtedly very singular, and it is difficult to conceive what can be the source of so widespread a formation of manganese. It is, of course, a matter of great difficulty to make anything like accurate analyses on ship-board. Mr. Buchanan is giving his careful attention to the whole subject of the chemical composition of the sea-bed, and I hope that the determination of the composition of a number of samples, when a favourable opportunity occurs, will throw additional light upon this and a number of other obscure points connected with the chemistry of modern geological formations.

Scalpellum regium, n. sp. (Fig. 1), is by far the largest of the known living species of the genus. The extreme length of a full-sized specimen of the female is 60 mm., of which 40 mm. are occupied by the capitulum, and 20 mm. by the peduncle. The capitulum is much compressed, 25 mm. in width from the occludent margin of the scutum to the back of the carina. The valves are 14 in number; they are thick and strong, with the lines of growth strongly marked, and they fit very closely to one another,

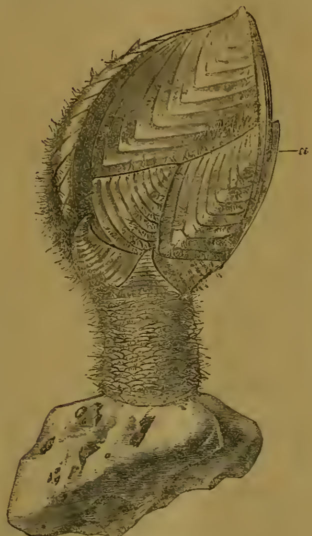

Fig. 1.

Fig. 2.

Fig. 1.—Scalpellum regium, Wy. Thomson. *a*, Males lodged within the edge of the scutum. Fig. 2.—Male of Scalpellum regium.

in most cases slightly overlapping. When living, the capitulum is covered with a pale-brown epidermis, with scattered hairs of the same colour.

The scuta are slightly convex, nearly once and a half as long as broad. The upper angle is considerably prolonged upwards, and, as in most fossil species, the centre of calcification is at the apex. A defined line runs downwards and backwards from the apex to the angle between the lateral and nasal margins. The occludent margin is almost straight. There is no depression for the adductor muscle, and there is no trace of notches or grooves along the occludent margin for the reception of the males; the interior of this valve is quite smooth. The terga are large, almost elliptical in shape, the centre of calcification at the upper angle. The carina is a handsome plate, very uniformly arched, with the umbo placed at the apex. Two lateral ridges, and a slight median ridge run from the umbo to the basal margin. The lower part of the valve widens out rapidly, and the whole is deeply concave. The rostrum, as in *Scalpellum vulgare*, is very minute, entirely

hidden during life by the investing membrane. The upper latera are triangular, the upper angle curving rather gracefully forwards; the umbo of growth is apical.

The rostral latera are long transverse plates lying beneath the basal margins of the scuta. The carinal latera are large and triangular, with the apex curved forwards very much like the upper latera, and the inframedian latera are very small, but in form and direction of growth nearly the same.

The peduncle is round in section and strong, and covered with a felting of light-brown hair. The scales of the peduncle are imbricated and remarkably large, somewhat as in *S. ornatum* Darwin. About three, or at most four scales, pass entirely round the peduncle. The base of attachment is very small, the lower part of the peduncle contracting rapidly. Some of the specimens taken were attached to the lumps of clay and manganese concretions, but rather feebly, and several of them were free, and showed no appearance of having been attached. There is no doubt, however, that they had all been more or less securely fixed, and had been pulled from their places of attachment by the trawl. On one lump of clay there were one mature specimen and two or three young ones, some of these only lately attached. The detailed anatomy of this species will be given hereafter, but the structure of the soft parts is much the same as in *Scalpellum vulgare*.

In two specimens dissected there was no trace of a testis or of an intromittent organ, while the ovaries were well developed; I conclude, therefore, that the large attached examples are females, corresponding, in this respect, with the species otherwise also most nearly allied, *S. ornatum*.

In almost all the specimens which were procured by us, several males, in number varying from five to nine, were attached within the occludent margins of the scuta, not imbedded in the chitinous border of the valve, or even in any way in contact with the shell, but in a fold of the body-sac quite free from the valve. They were ranged in rows, sometimes stretching—as in one case where there were seven males on one side—along the whole of the middle two-thirds of the edge of the tergum.

The male of *Scalpellum regium* (Fig. 2) is the simplest in structure of these parasitic males which has yet been observed. It is oval and sac-like, about 2 mm. in length by ·9 mm. in extreme width. There is an opening at the upper extremity which usually appears narrow, like a slit, and this is surrounded by a dark, well-defined, slightly raised ring. The antennæ are placed near the posterior extremity of the sac, and resemble closely in form those of *S. vulgare*. The whole of this sac, with the exception of a small bald patch near the point of attachment, is covered with fine chitinous hairs arranged in transverse rings. There is not the slightest rudiment of a valve, and I could detect no trace of a jointed thorax, although several specimens were rendered very transparent by boiling in caustic potash. There seems to be no œsophagus nor stomach, and the whole of the posterior two-thirds of the body in the mature specimens was filled with a lobulated mass of sperm-cells. Under the border of the mantle of one female there were the dead and withered remains of five males, and in most cases one or two of the males were not fully developed; several appeared to be mature, and one or two were dead, empty, dark-coloured chitine sacs.

On Wednesday, June 18, we resumed our course with a fine breeze, force 5 to 7, from the south-east. In this part of our voyage we were greatly struck with the absence of the higher forms of animal life. Not a sea-bird was to be seen, with the exception of a little flock of Mother Carey's chickens, here apparently always *Thalassidroma wilsoni*, which kept playing round the ship, on the watch for food, every now and then concentrating upon some peculiarly rich store of offal as it passed astern, and staying by it while the ship went on for a quarter of a mile, fluttering above the water and daintily touching it with their feet as they stooped and picked up the floating crumbs, and then rising and scattering in the air to overtake us and resume their watch.

The sea itself in the bright weather, usually under a light breeze, was singularly beautiful—of a splendid indigo-blue of varying shades as it passed from sunlight into shadow, flecked with curling white crests; but it was very solitary: day after day went by without a single creature (shark, porpoise, dolphin, or turtle) being visible. Some gulf-weed passed from time to time, and bunches of a species of *Fucus*, either *F. nodosus* or a very nearly allied form, evidently living and growing, and participating in the wandering and pelagic habits of *Sargassum*. The floating islands of the gulf-weed, with which we have become familiar as we have now nearly made the circuit of the "Sargasso Sea," are usually from a couple of feet to two or three yards in diameter, sometimes much larger; we have seen, on one or two occasions, fields several acres in extent, and such expanses are probably more frequent nearer the centre of its area of distribution.

They consist of a single layer of feathery bunches of the weed *Sargassum bacciferum*, not matted together, but floating nearly free of one another, only sufficiently entangled for the mass to keep together. Each tuft has a central brown thread-like branching stem studded with round air-vesicles on short stalks, most of those near the centre dead, and coated with a beautiful netted white polyzoon. After a time vesicles so encrusted break off, and where there is much gulf-weed the sea is studded with these little separate white balls. A short way from the centre, towards the ends of the branches, the serrated willow-like leaves of the plant begin, at first brown and rigid, but becoming, farther on in the branch, paler, more delicate, and more active in their vitality. The young fresh leaves and air-vesicles are usually ornamented with the stalked vases of a *Campanularia*. The general colour of the mass of weed is thus olive in all its shades, but the golden olive of the young and growing branches greatly predominates. This colour is, however, greatly broken up by the delicate branching of the weed, blotched with the vivid white of the encrusting polyzoon, and riddled by reflections from the bright blue water gleaming through the spaces in the network. The general effect of a number of such fields and patches of weed, in abrupt and yet most harmonious contrast with the leaves of intense indigo which separate them, is very pleasing.

These floating islands have inhabitants peculiar to them, and I know of no more perfect example of protective resemblance than is shown in the gulf-weed fauna. Animals drifting about on the surface of the sea with such scanty cover as the single broken layer of the seaweed, must be exposed to exceptional danger from the sharp sea-birds hovering above them, and from the hungry fishes searching for prey beneath, but one and all of these creatures imitate in such an extraordinary way, both in form and colouring, their floating habitat, and consequently one another, that we can well imagine their deceiving both the birds and the fishes. Among the most curious of the gulf-weed animals is the grotesque little fish, probably *Antennarius marmoratus*, which finds its nearest English ally in the "fishing frog" (*Lophius piscatorius*), often thrown up on the coast of Britain, and conspicuous for the disproportionate size of its head and jaws, and for its general ugliness and rapacity. None of the examples of the gulf-weed *Antennarius* which we have found are more than 50 mm. in length, and we are still uncertain whether such individuals have attained their full size. It is this little fish which constructs the singular nests of gulf-weed bound in a bundle with cords of a viscid secretion, which have been already mentioned as abundant in the path of the gulf-stream.

Scillæa pelagica, one of the shell-less mollusca, is also a frequent inhabitant of the gulf-weed. A little short

tailed crab (*Nautilograpsus minutus*) swarms on the weed and on every floating object, and it is odd to see how the little creature usually corresponds in colour with whatever it may happen to inhabit. Mr. Murray, who has the general superintendence of our surface work, brings in curious stories of the habits of these little crabs. We observe that although every floating thing upon the surface is covered with them, they are rarely met swimming free, and that whenever they are dislodged and removed a little way from their resting place, they immediately make the most vigorous efforts to regain it. The other day he amused himself teasing a crab which had established itself on the crest of a *Physalia*. Again and again he picked it off and put it on the surface at some distance, but it always turned at once to the *Physalia* and struck out, and never rested until it had clambered up into its former quarters.

On Thursday, the 19th, we sounded in 2,750 fathoms in a grey mud containing many foraminifera. Position of the ship at noon, lat. 35° 29′ N., long. 50° 53′ W.

The wind now gradually freshened, and for the next three days we went on our course with a fine breeze, force from 4 to 7, from the southward, sounding daily at a depth of about 2,700 fathoms, with a bottom of reddish grey ooze. On Tuesday the 24th the trawl was put over in 2,175 fathoms, lat. 38° 3′ N., long. 39° 19′ W., about 500 miles from the Açores. As in most of the deep trawls on grey mud, a number of the zoœcia of delicate branching polyzoa were entangled in the net. One of these on this occasion was very remarkable from the extreme length (4 to 5 mm.) of the pedicels on which its avicularia were placed. Another very elegant species was distinguished by the peculiar sculpture of the cells, reminding one of those of some of the more highly ornamented *Lepraliæ*.

WYVILLE THOMSON

(*To be continued.*)

THE FRENCH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE

THE second session of the French Association was opened at Lyons last Thursday, by an inaugural address from the President, M. de Quatrefages, who pointed out the almost inconceivable advance of Science during the past century, and the importance of Science in education.

In speaking of scientific education, the President said that the devotees of literature accused Science of stifling sentiment and imagination; she kills, say they, the ideal and stunts intelligence by imprisoning it within the limits of reality; she is incompatible with poetry. The men who speak thus have never read Kepler the astronomer, Pascal the geometer, Linnæus the naturalist, Buffon the zoologist, Humboldt the universal *savant*. What! says the President, Science stifle sentiment, imagination, she who brings us every hour into the presence of wonders! She lower intelligence, who touches on all the infinities! When *littérateurs* and poets know Science better, they will come and draw from her living fountain. Like Byron of our time, like Homer of yore, they will borrow from her striking imagery, descriptions whose grandeur will be doubled by their truth. Homer was a *savant* for his time. He knew the geography, the anatomy of his era; we find in his verses the names of islands and capes, technical terms like *clavicle* and *scapula*. None the less he wrote the Iliad.

No, the study of Science will never suppress the genius of an inspired poet, of a true painter, of a great sculptor. But she will bring more light to the path of an erring soul. She will perhaps transform into a wise man, or at least into a citizen useful to himself and others, one who without her would only have been one of those pretended incomprehensible geniuses, destined to perish of misery, of impotency, and of pride. While fully admitting the important place of literature in education, he would wish to see children initiated at an early age into the facts, the ideas, the methods of Science.

Governments, such as they have hitherto been, have almost always acted as if they had no need for the men who study Nature and her forces. But when any critical or important event occurs, then it is found necessary to appeal to them. Of whom are the juries of International Exhibitions composed? No doubt each State sends its worthy merchants, its tried chiefs of industry, its eminent agriculturists, but it also, and above all, sends its men of science. At these important times peoples are comparing their real strength, and each feels that it is for its honour in the present and its prospects in the future that the truth should appear; and to enlighten them, whether it be concerning cannons or silk-manufactures, telescopes or crystals, jewellery or hardware, it is felt that Science is indispensable, and men of science are appealed to.

But once the Exposition is closed, the State leaves the men of science to return to their studies. I wish, said M. de Quatrefages, it kept them in the service of their country. These men whom we ask to understand and judge of wonders would certainly be able to show how to produce them. When Science is everywhere, it would certainly not be useless to Government to have it in their power to be enlightened at any time on scientific questions. Although less pressing, less imperious than in the days of peril, the wants of agriculture, of industry, of commerce, like those of the army and navy, do not change their nature. Why wait the necessity for appealing to the *savants*?

A day will come when every great Administration will have its Consulting Committee, composed almost exclusively of men of science, and then many mistakes will be avoided, and many forces utilised which are at present lost. But in order that such an institution should be born and developed, it is necessary that the function of Science be universally comprehended and accepted. To attain this result is one of the chief aims of the French Association.

CHRISTOPHER HANSTEEN

ON the 11th of April last, Hansteen died at Christiania at the advanced age of 88, having been born on the 26th September, 1784. On leaving the cathedral school of Christiania, where he received his early education, he entered the University of Copenhagen in 1802, as a student of law, which, however, he soon abandoned for the more congenial study of mathematics. In 1806, he began his work as a public instructor in the capacity of mathematical tutor in the gymnasium of Fredricksburg, in the island of Zealand, and there he began also his life work as an original investigator by instituting researches into terrestrial magnetism. He first acquired distinction by taking the prize which had been offered for the best essay on this subject, by the Royal Society of Science of Copenhagen; and shortly thereafter, viz. in 1814, was appointed to the chair of Astronomy in the University of Christiania, which had been recently founded by Frederick VI. of Norway.

His great work, entitled "Untersuchungen über den Magnetismus der Erde," was published in 1819, at the expense of the King. This work was illustrated with an Atlas of Maps, and was the most satisfactory collection of observations on the variations of the needle, and was besides distinguished for its broad philosophical generalisations. In the further prosecution of his physical researches, he made his well-known journey into Siberia as far as Kiachta and Irkutsk, accompanied by Erman and Due, the expenses of this journey being liberally defrayed by the Norwegian Government. The establish-

ment, on the recommendation of Humboldt, of the ten magnetical and meteorological observatories, by the Emperor of Russia, was one of the most valuable fruits of this journey.

Among Hansteen's contributions to our knowledge of magnetism, may be mentioned the establishment by him of a period of 11·1 years as the length of the periodicity of the magnetic declination—a cycle which has recently assumed such remarkable significance in connecting astronomical with meteorological and other terrestrial phenomena.

Soon after his return from Siberia, the Government voted the necessary sum for building an astronomical and meteorological observatory at Christiania, which was erected under Hansteen's direction. This observatory has done much good work, of which the meteorological department deserves very special commendation. The trigonometrical and topographical survey of Norway, which was begun in 1837, was conducted under Hansteen's superintendence.

In 1856, the completion of his fifty years public services was celebrated, and a medal was struck in commemoration of the event. Shortly after this he ceased to lecture publicly, and in 1861 retired from public duty.

THE NOTORNIS OF LORD HOWE'S ISLAND

THE last number of the *Ibis* (July 1873, pl. x.) contains a representation of a very interesting bird, about which, though discovered and described in the last century, naturalists have for a long time been doubting. This is the species said to be first mentioned by Callam in 1783 (Voy. Bot. Bay), and subsequently figured in the works of John White (Journ. Voy. New South Wales, p. 238, App.) and Governor Phillip (Voy. Bot. Bay, p. 273, pl.), and designated by Latham (Ind. Orn. ii. p. 768) *Gallinula alba*. No specimens are known to have been brought to Europe for upwards of *eighty* years, and only two are believed to exist in museums—one in that of Liverpool, which was figured by White, and the other in Vienna, now for the first time portrayed. The species is most likely extinct in Norfolk Island, but a passage in a pamphlet by Mr. Edward Hill, published at Sydney in 1870, seems to show that it may still exist in that of Lord Howe—though, if so, doubtless on the verge of extermination through the pigs, with which the island is said to be overrun, for the bird is believed to be unable to fly. Should any examples be still living, it would certainly be better that their remains should be placed in our museums, than that they should contribute to the formation of pork; and I write these lines that they may attract the attention of some Australian readers of NATURE, who may be disposed to do a good turn to the University of Cambridge.

This bird, which has been variously assigned to the genera *Gallinula* (moor-hen), *Fulica* (coot), and *Porphyrio*, is now referred to the genus *Notornis*, containing only one other species, the "Takahe" of New Zealand (*N. mantelli*)—itself nearly, or quite, extirpated. It was about the size of a barndoor-fowl, with the bill and legs red. The Viennese specimen seems to be entirely white; the example at Liverpool is mottled with purple, but not enough to gainsay the name of "White Bird," by which it seems to have been known both in Norfolk and Lord Howe's Islands. It would no doubt, if taken alive, be easily kept in confinement, and I need scarcely say how highly a living example would be valued by the Zoological Society; but this is perhaps more than can be reasonably hoped for, and, so far as I am concerned, I should be well content with a specimen in spirit, or a skin with all the bones accompanying it, for the Cambridge Museum.

I may perhaps be allowed to conclude by remarking that the history, and especially the distribution of the family of birds, to which the subject of this notice refers is indeed worthy of far more attention than they have hitherto received, and could that accomplished zoological writer who has lately in the columns of a sporting contemporary made the not very distant family of *Gruidæ* the theme of an admirable series of essays—far probably from being fully appreciated by his readers—be induced to employ his pen on the *Rallidæ*, the results would be of the greatest interest. The Rails—employing the word in a very wide sense—are cosmopolitan in the highest degree. Some of the best known genera have their representatives all over the world, occurring even in oceanic islands, where birds generally are so scarce—*Gallinula* and *Fulica*, for instance; and some at least of the former, when they get to such remote spots, seem to lose their volatile powers, though otherwise undergoing but little change, as witness the *G. nesiotis* of Tristan d'Acunha, made known a few years ago by Mr. Sclater, and a form still undescribed, of which three examples were obtained by my brother from Denis Island, an outlier of the Seychelles group (*Ibis*, 1867, p. 358). Then there is a genus equally flightless, which has lately been restored to light and knowledge, but, alas! too late for us to know it in the flesh. This is the *Aphanapteryx*, which survives only in a few bones, recovered from the mud of a Mauritian lake, and now in the Cambridge Museum, a painting at Vienna, and a few notices by early voyagers—a bird with a long bill and dishevelled plumage, almost, it would seem, like that of the *Apteryx*. In the opposite direction almost, as to structure, we have *Tribonyx*; but I should occupy far too much space were I now to dwell upon even the chief forms of the family. From whatever point of view it be regarded, it will be found one of the most interesting in the whole series of birds.

ALFRED NEWTON

ASTRONOMICAL ALMANACS *

II.

II.—*The "Connaissance des Temps," under the direction of the Academy of Sciences*

THE first to whom the Academy entrusted the editorship of these Ephemerides was Lieutaud.

The only real modification introduced into the volume was the substitution, for the table of refractions published by Lefebvre, of a table of the refractions of Cassini, giving the values of that quantity in minutes and seconds for all degrees of height, from 0° to 90°. The book was also somewhat increased in size. In 1707 Lieutaud introduced into the *Connaissance des Temps* a notice of the occultations of stars, the observation of which is of use in determining longitudes. Lieutaud edited the *Connaissance des Temps* till 1730, when it passed into the hands of a young academician, Louis Godin.

Godin, a pupil of Delisle, was born at Paris on February 28, 1704, and entered the Academy as *élève* at the age of 21 years. He was then known only by a keen desire for knowledge and a strong predilection for astronomy. On taking the direction of the *Connaissance des Temps*, he suppressed the aspects of the planets, which were useless, and introduced the right ascension of the sun for every day of the year; calculated this co-ordinate and the declination to a second, and added the eclipses of the satellites of Jupiter, so that the *Connaissance des Tembs* contained from this time the announcement of the eclipses of the superior satellites.

In 1735 Godin set out for Peru for the purpose of measuring with Bouguer and La Condamine an arc of one degree of the meridian, and to Jean-Dominique Maraldi, grand-nephew of Cassini the elder, was committed the care of the *Connaissance des Temps*. He enriched the work with the configuration of the satellites of Jupiter for every day in the year, but he suppressed the notice of occultations,

* Continued from p. 312.

agreat mistake, certainly; though perhaps these phenomena were of little service in his time. Having become a *pensionnaire* of the Academy in 1760, he resigned the editorship of the *Connaissance des Temps* to Joseph-Jerôme Le François de Lalande.

De Lalande, born at Bourg-en-Bresse, July 11, 1732, was sent at the age of 20 to Berlin, under the patronage of Le Monnier, his master, to take observations of the moon, which, combined with those which La Caille at that time effected at the Cape of Good Hope, were the means of giving the parallax of that planet. On his return he was presented to a place vacant for many years in the Academy, and shortly after, in 1760, he was entrusted with the editorship of the *Connaissance des Temps.* A distinguished astronomer, possessing a thorough knowledge of all the advances which had been made during later years in astronomical science, Lalande very much improved the work of which he had charge. We shall mention the most important of the changes which are due to him.

His first care was to take for the basis of his calculations new tables, more exact than those which Godin had continued to employ. He employed for the sun the tables of the Abbé of La Caille; for the moon, those of Tobie Mayer*; for the planets, the tables of Cassini; and for the eclipses of the satellites of Jupiter, those of the Swede Wargentin, of which he had published a new edition. The rising of the sun and the planets is calculated for the true noon of each day; but, says Lalande, "the *Connaissance des Temps* being intended mainly for astronomers, the positions of the moon are given for the instant of her passage across the meridian." The following year, however, "on account of the inconveniences attending such a mode of indication," this astronomer resolved to give the longitudes for midday and midnight of each day. Finally, in a short and well-written memoir appended to the *Connaissance des Temps,*† he investigated the different methods for finding the longitude at sea by a single observation of the moon. Some years later he restored the announcement of the occultation of stars.

In 1774, the *Connaissance* received from Jerôme Lalande a most important improvement, which was the means of making this work, hitherto almost exclusively intended for astronomers, of great use to mariners. But, before stating in what this modification consisted, some historical details are necessary concerning one who was the real pioneer, and at the same time one of the glories of French astronomy in the 18th century.

In 1737, the *savant* Fouchy presented to Cassini of Thury, son and successor of the first director of the Observatory of Paris, celebrated for his fine work on "The Size and the Figure of the Earth," a young deacon of 23 years, who, alone, without instruments and almost without books, had acquired a remarkable astronomical education. Cassini welcomed the *protégé* of Fouchy, lodged him at the Observatory, and allowed him to take part in his work. This young Abbé was Nicolas-Louis de la Caille, born on March 15, 1713, at Rumigny, near Rozoy, in Thiérache. J. D. Maraldi, grand-nephew of Cassini the first, and who also lived at the Observatory, became his friend, and a year after his arrival (1738), La Caille made along with him the geographical description of the coast of France, from Nantes to Bayonne; in 1739 La Caille took part in the work connected with the meridian of France.‡ Shortly after, Dr. Robbes nominated him professor of mathematics at the Mazarin College. He instituted a small observatory where he made a very large number of observations of rare precision. In 1741, at the age of 27 years, La Caille entered the Academy of Sciences.

In 1744 the astronomer of the Mazarin College published the first volume of a series of Ephemerides, entitled "Ephémérides des monuments célestes depuis 1745 jusq'en 1754," in which he was the first to give—and Lalande afterwards imitated him in the *Connaissance des Temps* of 1760—the distance of the sun at the equinox, or, what amounts to the same thing, the right ascension of the sun in time.

Some years later, in 1749, La Caille proposed to the Academy that he should spend a year at the Cape of Good Hope, for the purpose of making an accurate catalogue of the stars of the southern sky, intended to replace the first rough sketch made in 1677, by Halley, at St. Helena; to measure the parallax of the moon, of Venus, and of Mars, by means of comparative observations made simultaneously in Europe; and finally to determine carefully the geographical position of the Cape of Good Hope.*

The proposal of La Caille was adopted, and the States-General of Holland having given their assent, La Caille set out in 1751, after having published the list of stars which he wished to be observed by the European astronomers, for the purpose of rendering his voyage fruitful in scientific results. We do not intend to recount all the incidents of this expedition. Let us, however, mention a fact which illustrates well the character of this astronomer, "reserved, modest, and disinterested." He received for his expedition, the purchase of instruments, and other expenses, for his maintenance and that of an artist, the sum of 10,000 livres; on his return, he found he had spent only 9,145 livres. He scrupulously carried back the balance to the royal treasury; the officials, surprised, would not accept it. "You require it," they said to him; "it will take it to remunerate you." Moreover, when he set out from the Cape, the minister had charged him to make maps of the Isles of France and of Bourbon, which were not comprised in the original plan, and "for which most others would have asked, and certainly obtained, a supplementary indemnity."†

The observations made during this expedition (1751 and 1752) by La Caille with his telescope of 26 inches focus, and an inch and a half aperture, were published by himself, and after his death, by Maraldi, in 1763, under the title, "Cœlum australe stelliferum, seu observationes ad construendum stellarum Australius catalogum institutæ, in Africa ad Caput Bonæ-spei, à Nicolao-Ludovice De La Caille."

A new edition of this catalogue was published in 1847, under the superintendence and at the expense of the British Association and the British Government, under the editorship of Messrs. Bailly and Henderson, the latter, at the time, Director of the Edinburgh Observatory.‡

But, besides, this voyage to the Cape of Good Hope had a most important result. During the two journeys, La Caille tested and compared all the methods employed till then to determine longitude at sea. Among these he noted that which the celebrated Halley had given in 1678, and which is based upon the observation of the distance of the moon from the sun or from a star. The experiments which he made in reference to it having convinced him of its excellence, he strongly recommended it on his return to France; and in his second volume of Ephemerides, which commenced in 1755, he proposed a Nautical Almanac, in which should be found, for every hour of the

* "Tabularum motuum solis et lunæ et longitudinum methodus pro nota."

† Lalande afterwards regularly followed the custom of accompanying the *Connaissance des Temps* with short astronomical memoirs, entitled "Additions to the *Connaissance des Temps.*" This custom has continued to the present day.

‡ The work done by Cassini de Thury, Maraldi, and La Caille, was published by La Caille in 1744, and bore the name of Cassini de Thury.

* La Caille also purposed to observe the length of the seconds pendulum, the variation of the magnetic needle, and finally the length of a degree of the meridian at the Cape. This has since been measured under the equator, under the Polar Circle, and in various places in Europe; but we do not yet know the value of any degree in the southern hemisphere.

† In the accounts which he rendered on his return, La Caille has put down only *five sous* for his daily expenses, and as much for those of a mechanician who accompanied him.

‡ The Association gave 200*l.* and the Government 1,000*l.* It is entitled "A Catalogue of 9,766 Stars in the Southern Hemisphere for the beginning of the year 1750, from the Observation of the Abbé de la Caille."

day, the distance of the moon from the sun and the stars. La Caille regretted that his other occupations would not permit him to compile this nautical Ephemerides himself. At a later time, in his treatise on navigation, he reverted to the same subject, and gave anew the sketch of his almanac, limiting himself to giving the distances every four hours for the meridian. His design was not followed. Lalande contented himself with analysing and discussing La Caille's method in the *Connaissance des Temps* for 1760. As to the French Marine, it was content to use "L'état du Ciel, calculé par Pingré et rapporté à l'usage des marins, 1754, 1755, 1756, et 1758." It was very different, however, in England.

(To be continued.)

SOUTH AFRICAN MUSEUM

THE *Cape Argus* for July 10 contains the report of the curator, Mr. Roland Trimen, of the South African Museum, for the previous half year. Many valuable additions have been made to the museum during that time, but its efficiency is very seriously crippled through want of funds, mainly due, we are sorry to say, to the parsimony of Government. We regret to see that the number of subscribers has seriously diminished from what it originally was, but the success of so valuable an institution should in no way be dependent on the capricious revenue to be derived from such a source. Let us hope that recent changes in the *personnel* of the Government will lead to greater liberality for this and for other scientific purposes. We cannot do better than give a few extracts from an excellent leader in the *Argus* on the Curator's report.

"Now that strong efforts are being made to forward the interests of education in the Colony, those institutions that aid in the work should not be neglected. We do not at present refer to colleges and schools, for these, whenever education is discussed, come prominently before the popular mind, but our remarks are directed rather to such places as museums, whose work in higher education of the kind required in modern days is of considerable importance . . . It has often struck us as rather a reflection on Cape Town that there is no Society here for the discussion of natural science subjects, and though we are aware of some obstacles to the successful working of such a body, we see no reason why they should not be overcome. In the capital of every Colony of which we have any knowledge, a Society of the kind exists, and indeed in the Cape itself there are towns that, in this respect at least, are ahead of the metropolis.

"But though we have no Natural Science Society in Cape Town, we have what, all things considered, may be said to be an excellent Museum. . . . The Museum was founded under the enlightened influence of the then Governor, Sir George Grey, in 1855, and in 1857 was incorporated by Act of Parliament. Its first trustees were Mr. Rawson, the Colonial Secretary at the time, Sir Thomas Maclear, the then Astronomer Royal, and Dr. Pappe, the then Colonial Botanist. On Dr. Pappe's death Mr. C. A. Fairbridge was appointed a trustee, and upon the resignation of Mr. Rawson, on his departure from the Colony, his place was filled by Mr. Southey, now Lieut.-Governor of Griqualand West. It will be thus seen that the Museum has from the first been under the management of trustees alike of scientific acquirements and business ability. In its first curator, Mr. Layard, it was extremely fortunate, and it had the advantage of his enthusiastic labours for the lengthy period of fifteen years.

"But though it has had the advantage of excellent management, the development of the institution has been seriously hindered from want of funds, and it has not received, either from the Legislature or the public, that pecuniary support necessary to secure the services of efficient officers and to meet the thousand and one expenses of cases, glass, chemicals, and the appliances and apparatus required in carrying out the work of a museum. It is a wise policy on the part of the Legislature to vote grants of money to such institutions in proportion to the pecuniary support received from the public, and if Parliament is to be induced to make a larger grant to the Museum, the private subscription list must be extended. The small sum of one guinea represents the subscription for a year, and we are quite sure, when it is known how much the institution stands in want of funds, the list of subscribers will become larger.

"Strangers who visit the Museum and who know how such things are managed elsewhere must smile when told that its curator is a clerk in the Civil Service, whose time is chiefly occupied in doing the work of a subordinate officer in the Colonial Office. We say this without any intention of disparaging the gentleman referred to, for his attainments in one branch of Science at least are universally admitted; but we do say that, if the South African Museum is to be anything like worthy of the name, and if it is to continue efficiently to perform the work so well commenced by Mr. Layard, its curator should devote the whole of his time and attention to the duties of that office. Under existing circumstances, that, however, is not to be expected, as the salary is not sufficient to induce any qualified gentleman to give up other positions for the sake of applying himself entirely to the work of the Museum.

"There are other matters connected with this institution to which we might draw attention, but until more public support is given to the Museum it would be a waste of time to refer to them."

GEOLOGICAL MAP OF AUSTRALIA AND TASMANIA *

GEOLOGICAL surveys have been proceeding, to a greater or lesser extent, in all the Australian colonies for several years, and in Victoria the work has been prosecuted so systematically, and with such success, that the main features of the surface geology of the country are comparatively well ascertained and mapped out. The example in this respect set by Victoria has been followed to a very considerable extent by Queensland, and in a lesser degree by several of the other colonies. A geological map of Australia has, however, never been issued. Such a work would be invaluable, and the materials obtained are quite sufficient to justify an attempt being made to carry it out. Such an attempt is now being made by the Mining Department of Victoria. Some months since the Hon. A. Mackay, Minister of Mines, put himself in communication with the Governments of the other colonies with the view of obtaining from them all the information in their possession respecting the geological characteristics of the territories over which they presided. The application was readily acceded to, and a large mass of materials has been since placed at the disposal of the Mining Department of Victoria. Under the direction of Mr. R. Brough Smyth, F.G.S., Secretary for Mines, this has been thoroughly digested and arranged, and is now being embodied in a map, which, when completed, as it will be shortly, will show at a glance the result of all geological surveys made in Australia and Tasmania up to the present time. As the value of such a work necessarily depends upon the accuracy of the observations upon which it is based, it may be well, before attempting a brief description of its main features, to indicate the source from whence the materials used in its compilation have been derived. The geological sketch

* From an article in the *Melbourne Argus*, July 7.

map of Victoria, exhibited by the Mining Department at the late Intercolonial Exhibition, and which contains the results of the latest surveys made in the colony, will be embodied in the general map. It was compiled by Mr. Brough Smyth from surveys made some years ago under the direction of Mr. A. R. C. Selwyn, at present director-general for the Geological Survey of Canada, but who formerly held a similar position in this colony, and from surveys made since by the officers of the mining department. It has been described "as the nearest approximation that can at present be made to a true representation of the rock masses which are exposed in this colony." The New South Wales Government have in preparation a geological map, which, it is expected, will be available for use before the general map is published.

The Queensland Government has been keenly alive to the importance of mapping out the immense mineral districts of that colony, and for some years has kept a staff of geological surveyors actively employed in the work. The information thus collected has been embodied in a series of elaborately-coloured and beautifully-executed maps, which have proved of great service in the compilation of the general map of Australia. An excellent sketch map, covering a considerable portion of the colony, has been obtained from the Government of South Australia. It was compiled under the direction of Mr. A. B. Cooper. It is especially valuable, as it embraces a great part of the populated districts. The country north of Encounter Bay, the most extensive mineral district in the southern portion, was examined and reported on by Mr. Selwyn many years ago, and a sketch map prepared by him is being used in compiling the new map. The same district has been very recently reported upon by Prof. Ulrich, at the request of the Government, and his observations are proving of great assistance.

Thanks to the energy of Mr. C. Gould, a son of the eminent naturalist, the geological characteristics of Tasmania were very accurately delineated during the time he was geologist for the colony. An excellent map was published under his direction, and he voluntarily made a number of additions to it a short time ago, when he learnt that a copy was to be transmitted to Victoria to be used in the preparation of the general geological map of Australia.

A large portion of the vast territory of Western Australia has been surveyed by Mr. H. Y. L. Brown, Government surveyor, but who was once attached to the geological staff of Victoria. This gentleman has produced a very beautiful sketch map of the S.W. portion of the colony, which has been extensively used by the compiler of the new map. It thus appears that every care has been taken to obtain the most accurate information at present available.

An examination of the map discloses facts of interest not only to geological students but to the public at large. The value of the map to men engaged in mining is too palpable to call for comment, as it shows at a glance the formations in which the precious metals occur. In rocks belonging to the primary or palæozoic group, gold, tin, antimony, silver, lead, and copper may be confidently searched for. The secondary or mesozoic rocks contain coal, while tin is frequently found associated with granitic rocks. Persons engaged in pastoral and agricultural pursuits will also derive advantage by consulting this map. A very little geological knowledge will tell them that in districts where the principal rock masses belong to the tertiary period they may look for well-grassed plains suitable for pasture. In areas where the volcanic rocks abound, rich soil, well adapted for agricultural pursuits, may be expected. The slatey ridges formed by the older silurian rocks, and the sparsely grassed mountains of granitic rock which abound in Western Australia, also convey a valuable lesson to the intelligent observer. One of the most prominent geological facts which the map discloses is, that a great metalliferous belt lies on each side of the main Cordillera from Cape Yorke to the southern point of Tasmania. It is composed chiefly of metamorphosed schists and granite rocks overlain in a considerable area by the newer palæozoic rocks and mesozoic coal-bearing strata. Another great belt appears to extend from Encounter Bay in South Australia towards the Gulf of Carpentaria. North of the 30th parallel of latitude the schists are overlain by tertiaries, and what Mr. Daintree considers to be rocks of the cretaceous age up to lat. 20° to 23°, where a large patch of metamorphic schist occurs. The whole tract west of the eastern metalliferous belt is occupied by tertiaries. Wide treeless plains, and what are called desert sandstones, abound. The vast tract of country known as Central Australia will have to be marked "unknown," as geological surveys have not yet been made of it. What is at present known of the geological character of the northern portion of South Australia will be mapped out. The Government of South Australia have furnished a very good map showing the palæozoic tract of Port Darwin, and from notes made by explorers the department has been able to lay down a large granitic tract also, as well as a large area covered with rocks of volcanic origin. The coal rocks are seen extending all along the coast from Port Curtis, in Queensland, in an almost unbroken line to Eden or Twofold Bay. They are especially prominent at Newcastle and Wollongong, in New South Wales. They again appear north of Corner Inlet, at Cape Otway, and can be traced in broken patches along the coast up to Glenelg, where they apparently terminate. Another interesting fact established by the new map is, that within the tertiary era connection has existed between Tasmania and the main land. There is a strict resemblance between the geology of Tasmania and the continent, and the chain of granite islands extending from Wilson's Promontory, the southernmost point of Australia, to Cape Portland, the northernmost point of Tasmania, have all their ridges capped with tertiaries, thus showing that within the tertiary period the island and the continent must have been connected. The main geological characteristic of Western Australia is the immense area occupied by granitic rocks, varied occasionally by patches of sandstone, especially on the southern coast line. A comparatively small part is occupied by a belt of metamorphic rocks to the east of Champion Bay. Volcanic rocks are also visible. A large granitic tract occurs in the basin of the Shaw River, east of Dampier's Archipelago. It appears that there has been a greater amount of denudation on the western side of the continent than on the eastern. Where the altitude is that of the Dividing Range, which varies from about 1,500 ft. to 7,000 ft., either granite, metamorphosed schists, or silurian rocks are found. Underneath the basalt or volcanic rocks in Queensland, as well as at Ballarat, the deep leads occur. It is curious to note that the deep leads of Queensland contain tin as well as gold. Wherever the dark red patch appears indicating granite, tin may be expected to be found. The extraordinary richness of the tin deposits of Queensland and New South Wales will probably cause the immense granitic tracts of Western Australia to be thoroughly explored. The middle belt of metamorphic schists which occurs in South Australia is as well known for its extensive copper mines as the eastern belt is for its gold.

The Mining department of Victoria has established a high reputation for the general excellence of the geological maps it has produced. The last effort will reflect equal credit upon the officers employed upon it. The rocks are shown in a descending order, and are easily recognised by the distinguishing colours with which they are tinted. A system of lettering the face of the map has also been adopted, which will fa-

cilitate the rapid identification of the rocks. In general appearance the map will more closely resemble those prepared in Germany or France than those compiled in England. As already mentioned, the responsible and onerous task of reducing the mass of materials obtained from so many different sources, and embodying the results of so many months of patient investigation, in the new map, has been performed by Mr. R. Brough Smyth. Mr. A. Everett, a draughtsman employed in the Mining department, has been entrusted with the duty of colouring the map, and Mr. R. Shepherd has performed the diffiult work of colouring it on stone.

NOTES

SIR SAMUEL and Lady Baker arrived at Cairo, last Sunday. All was well.

THE twenty-second session of the American Association for the Advancement of Science commenced its meetings at Portland, Maine, on Wednesday, 20th inst. Prof. Lovering, of Cambridge, is president for the year.

THE discovery is announced, from America, of another small planet, No. 133, by Prof. Watson, of the Ann Arbor Observatory.

THE session of the Iron and Steel Institute at Liége was brought to a close on Thursday, on which evening the King of the Belgians gave the members a grand reception at Brussels. There was an interesting discussion on Wednesday morning between Mr. Bulgenbach and Mr. Bell at the Institute, on the subject of the construction of high furnaces. Papers were read relative to various technical matters, and the President read a paper upon the extension of commercial relations with China. In the afternoon more than 450 excursionists paid a visit to the factory of Messrs. Cockerill at Seraing. Several speeches were made, and the visitors, who were most cordially received, remained four hours. It has been decided that the Congress should meet in 1874 in Philadelphia, and in 1875 in England. A very interesting paper was read at one of the meetings by M. Julien Deby, C.E., "On the Rise and Progress of the Iron and Steel Industries in Belgium," in which he said :—"We are very ignorant of the state of things in this country prior to the arrival of Julius Cæsar. Archæological discoveries of quite recent date, still unpublished, seem to indicate that at the period of the great Roman conqueror's invasion Iron had already been made in Belgium, while it was yet unknown to the inhabitants of the British Islands. The oldest records we have consist in vast deposits of cinder which cover many acres of ground, and are situated at Niew Rhode, between Louvain and Aerschot, in Brabant, as well as at Tessenderloo, in the Antwerp campagne, where they generally occupy the top of the many ferruginous hillocks of that region. Along with these accumulations of iron cinder are found flint arrow-heads and fragments of coarse pottery, characteristic of the earliest dawn of civilisation, and which must have belonged to the old pre-historic workers of these deposits. At a later period, and during the Roman dominion, iron was produced in very many places in Belgium. Immense heaps of cinder are to this day scattered in many parts of the country, and several of these are being profitably worked in the neighbouring blast furnaces."

THE meetings of the British Archæological Association at Sheffield were brought to a close on Saturday. The time has been spent by the members in visiting most of the places of archæological interest in the district during the day, and in listening to papers read in relation to the places visited, as well as on other subjects. On Wednesday night, at a *conversazione* in the Cutlers' Hall, Mr. R. N. Phillips read a paper on the "Manufacture of Hardware by Celts and Romans," illustrated by fine specimens in bronze of various degrees of advancement, a baked clay melting-pot, and a bronze ingot. He adduced evidence of mining and smelting by Romans, and stated their wood-smelted iron to be of unequalled malleability. He suggested that the Romans held Britain for the sake of its mineral wealth; their extensive beds of scoriæ in the Forest of Dean were still so rich in ironstone that they were being re-smelted. Mr. T. Morgan read a paper on the "Earliest Tribes of Yorkshire," and Mr. Alfred Wallis one on the "Pre-historic Remains on the Derbyshire Borders."

AT the meeting of the Somersetshire Archæological and Natural History Society held at Wells last week Dr. Beddoe gave a brief sketch of the ethnological history of the county, and showed its bearings upon the physical aspect of the population at the present day. We learn from the paper that the people of the eastern half of the county have, on the whole, broader heads, lighter hair, and darker eyes than those of the western half. In all these respects the eastern men approach more to the ordinary English, the western to the Irish, standard. The mixed blooded inhabitants of the towns appear to be lighter as to both eyes and hair than the people of either division. The fair and handsome Frisian type is pretty common in the north of the county. In the hilly south-eastern region about Wincanton dark complexions and dark or even black hair attest the late and imperfect Saxonisation of the country; the same may be said of the Quantocks. About Minehead and Dunster, perhaps from the less fixity of the population induced by seafaring, there is more evidence of mixture of blood; and in Exmoor and in some villages of Mendip the narrow skull, prominent jaws, and bony frame of the Gaelic type and the Turanian oblique eye and pyramidal skull crop up.

DR. BELL PETTIGREW, F.R.S., has been appointed Lecturer on Physiology at the School of Medicine, Surgeons' Hall, Edinburgh.

THE Secretaries of Section C (Geology) of the British Association request the attention of authors to the rule requiring the early transmission of papers. In order that the work of the Organising Committee may be completed in time, all papers and reports, accompanied by abstracts, should be forwarded to the General Secretaries not later than September 4.

WE are indebted to Mr. G. Gore, F.R.S., for a copy of a reprint of an able article of his on the "National Importance of Scientific Research," which appeared in a recent number of the *Westminster Review*. We are glad to have the opportunity of drawing attention to Mr. Gore's paper, as it forcibly expresses the view we have so persistently advocated in our own columns. Mr. Gore, after showing that the pursuit of pure Science is rarely rewarded in this country, points out that it is the duty of the State to provide and pay for pure scientific research, for the following reasons :—"Because the results of such labour are indispensable to national welfare and progress; because the results are of immense value to the nation, and especially to the Government; because nearly the whole pecuniary benefit of it goes to the nation, and scarcely any to the discoverer; because research cannot be efficiently provided for by means of voluntary effort; and because there appears to be scarcely any other way (except by application of University revenues) in which discoverers can be satisfactorily paid for their labour." At present, as the writer states, the men paid the highest are not those who discover knowledge, but those who use and apply it. The reason for this apathy of the public as regards scientific work is, as Mr. Gore shows, clearly traceable to a widespread and lamentable ignorance of the nature and value of scientific inquiry. To diffuse natural knowledge among all classes of society is therefore a great duty at the present time.

THE Philadelphians are hard at work preparing for their Centennial Exhibition to be held in 1876. 200*l*. each for the ten best designs for an appropriate building had been offered, and forty plans have now been sent in. The Centennial Commission having in charge the inauguration and conduct of the Great Exhibition, have already made most commendable progress. Committees from their number, having in charge special departments of the vast scheme, are in constant session, and the general outline of the work seems to have been fully developed. The site for the buildings used for the occasion has already been selected in Philadelphia's beautiful park, and the formal transfer of the ground by the city authorities to the control of the Centennial Commissioners took place, with the imposing ceremonies befitting the occasion, on July 4. The decoration of the ground for the purpose, the planting of shade trees, &c., will be taken in hand at once.

AMONG the appropriations made by the State of New York for the State Cabinet of Natural History are the following enumerations:—Hall of Natural History, cleaning, repairs, &c., 3,000 dols.; for the increase of the zoological collection, 1,000 dols.; assisting in arranging duplicate fossils and minerals for distribution, 1,500 dols.; salary of botanist, 1,500 dols.; for the use of the Cabinet of Natural History, 10,000 dols., making an aggregate of 17,000 dols. The Board of Regents of the University receive 6,500 dols.

THE offer of free lodging in the Rudolphinum during the Exhibition at Vienna has been responded to by no fewer than 2,412 teachers. Of these 418 have been selected, viz.:—207 Austrians, 99 Germans, 36 Italians, 20 Englishmen, 14 Dutchmen, 13 Swedes, 12 Danes, 10 Swiss, 7 Russians, 3 Belgians, and 2 Spaniards.

THE Committee appointed by the Birmingham Natural History and Microscopical Society to carry out the proposed Marine Excursion have, as nearly as possible, completed all the necessary arrangements. A yacht has been hired for six days, commencing Sept. 1, for a very moderate sum. Mr. A. W. Wills has made a large-sized dredge, which he has kindly presented to the Society. The small dredges belonging to the President and Mr. Wills will also be available for the excursion. With the view of rendering the dredging operations scientifically interesting and valuable, it is proposed to use a Miller-Casella thermometer with copper case, similar to those supplied for the *Porcupine* and *Lightning* expedition. Dredging operations, and the management of the yacht, will be entirely under the direction of the President and Mr. Wills, who will determine the hours of sailing and returning, the places to be visited, &c. &c. In addition to those made in the yacht, excursions to places of interest in the neighbourhood will be planned at intervals during the expedition. Very satisfactory arrangements have been made as to accommodation. The proposed excursion is an experiment which, if successful, may be repeated on a larger scale at some future time.

THE United States screw steamer *Juniata*, of 828 tons burden, left New York on the 24th of June, bound to Greenland, on her mission of rescue to the crew of the *Polaris*. She is in charge of Commander Braine, with a picked crew, and has been fitted out with every appliance needed for the success of her object. She reached St. Johns, Newfoundland, on June 30, and immediately went into the dock for the purpose of being properly sheathed with iron, and otherwise strengthened and refitted. As soon as this was completed she left for Disco, on July 9, where, or at Upernavik, she will wait until the arrival of her consort, the *Tigress*. The *Tigress*, it will be remembered, is the Newfoundland sealing steamer which rescued a part of the crew of the *Polaris* from the ice, and was purchased by the Secretary of the Navy as a relief vessel for the remainder of the party, as being better fitted for this end than any vessel that could be properly prepared in time for departure during the present summer. She reached New York on June 28, and was immediately examined by proper officers of the navy, who decided at once what alterations and repairs to put upon her. The *Tigress* is 165 ft. in length, has 28 ft. breadth of beam, and 16 ft. depth of hold, draws 13 ft. of water, and has a capacity of 463 tons. She has been placed under Commander Greer, lately of the Naval Academy, and is accompanied by Captain Tyson, late of the *Polaris*, as ice-master. The *Tigress* left Brooklyn on July 14, and arrived at St. Johns on July 23, where, like the *Juniata*, she will take in additional supplies, and then proceed northward. She is prepared to remain two years in the North if necessary, although it is hoped that she will return during the present season, convoying the *Polaris*.

THE second annual report of the Board of Commissioners of the Department of Public Parks in New York, is partly devoted to the condition of the Menagerie in Central Park, which has increased considerably in size during the last year. A catalogue is appended of the animals contained in the collection, which is on exactly the same plan as Mr. Sclater's carefully constructed List of Animals in the Zoological Society's Gardens in Regent's Park.

IN Part V. of Dr. Brown-Sequard's new "Archives of Scientific and Practical Medicine," there is an excellent analysis of some of the recent researches on the localisation of the cerebral functions, including an account of the experiments of Nothnagel, Gudden, and others. We hope next week to be able to give an abstract of the paper.

THE death of the Rev. Peter John de Smet, of the Society of Jesus, is announced as having taken place at St. Louis on May 23—an event which is worthy to be noted in a scientific point of view. Although not himself a special student of natural science, numerous collections made at his request and under his direction, and transmitted to museums at home and abroad, have borne witness to his tastes; and it is even stated that he has left behind him a manuscript record of his life, in which are embraced important notes of the habits and customs of the Indian tribes of the West, and of the physical condition and natural history of the regions inhabited by them.

THE Fourth Part of the illustrated work by Mr. Hermann Strecker, of Reading, Pennsylvania, upon the Lepidoptera has just been published, and contains figures and descriptions of quite a large number of species, illustrated by one plate. Among other species is included a new butterfly (*Satyrus hoffmanni*), obtained by Dr. Hoffmann at Owen's Lake, in Nevada.

THE *Journal of the Society of Arts* for August 22 contains a report on steel as represented at the International Exhibition, by Mr. William Baker.

A LETTER appears in the *Times* of Tuesday, from Mr. Richard Potter, one of the party from Mr. Leigh Smith's Arctic Expedition, by the Spitzbergen route. It is dated Trenerenberg Bay, July 4, and says:—"The *Polhem* came in here last night, and is going away again to-day. She is going home in about three weeks, I believe. We fell in with the *Samson* two days ago. We have been up to the Seven Islands, lat. 80° 50′, but there is too much ice to go farther North at present. Prof. Nordenskiöld and the other men who tried to get North in boats could not get farther than 80° 35′ lat., and then, finding the ice too rough for sledging, crossed the north-east land, and returned by Hinlopen Straits. They must have had a bad time of it, as there were

snowstorms fifty out of sixty days. The bay where we are now is where Parry left the *Hecla* when he went North on sledges. It is anything but a fertile place, as the low ground is all one great swamp, and there is a lot of snow on the ground still. We are going to stop here to take in water, and to get the provisions and coals out of the *Samson*."

The additions to the Zoological Society's Gardens during the last week include a Naked-footed Owl (*Athene noctua*), European, an Egyptian Vulture (*Neophron percnopterus*), and two Buzzards (*Buteo tachardus*), from Africa, presented by Mr. S. G. Reid and Lieut. Denison; a Golden Eagle (*Aquila chrysaëtus*), European, presented by Mr. A. W. Tait; a Paradoxure (*Paradoxurus typus*) from India, presented by Mr. A. F. Adey; a Mantchurian Crane (*Grus montignesia*) from N. China; a Wild Pig (*Sus scrofa*) from N. Africa; three Common Guillemots (*Uria troile*), British; a White-backed Piping Crow (*Gymnorhina leuconota*) from Australia, deposited, and four Gambel's Partridges (*Callipepla gambelii*) hatched in the Gardens.

SCIENTIFIC SERIALS

Der Naturforscher for July 1873, contains, among other interesting matter, an account of observations by Herr Nägeli, among plants in Alpine regions, as to the production of closely-related plant forms. He is led to conclude, (in opposition to the common view), that association is more favourable to the formation of species, than isolation. There are also botanical papers on the assimilation of air-plants under water, and the opening and closing of flowers. In physics and chemistry we have M. Amagat's recent important experiments on the expansion and compressibility of gases, and those of Troost and Hautefeuille on isomeric and allotropic transformations; a notice of M. Bichat's investigation of the influence of aggregate state on magnetic rotatory power, &c. M. Bichat has ascertained a decrease of this power as temperature rises, and entire disappearance of it in the state of vapour. Some striking facts with regard to the meteorological differences between northern and southern hemispheres are from a paper by Prof. Dove to the Berlin Academy. In physiology there are notes on the place of decomposition of albumen in animal bodies, and on the significance of common salt in the animal economy. Astronomy and technology are also represented, and there is a good selection of *Kleinere Mittheilungen*.

The current number of the *Ibis* commences with an article on the "Ornithology of Sardinia," by Mr. A. B. Brook, which is one of a series on that subject. The part before us includes the Woodpeckers, their allies, the Swifts, and some Passerine birds, among which are *Melizophilus sardus*, *Bradypterus cetti*, and the Corvine birds. Mr. R. Swinhoe describes the habits and plumage of the Rosy Ibis of China and Japan (*Ibis nippon*). He also notes points in its visceral anatomy, comparing them with the corresponding structures in the common Heron, in order to show that the affinities supposed by some to exist between the two birds are but slight. An editorial note verifies the conclusion that the Ibis and Spoonbill are intimately related, and differs justly from the author's conjecture that the former bird is related to *Tantalus*, which is a true Stork.—Mr. J. H. Gurney gives a tenth additional list of birds from Natal, including several species from the rich collection of Mr. R. B. Sharpe. Mr. J. E. Harting contributes a paper on *Charadrius pecuarius* of Temminck, in which it is shown that this bird is the smaller of the two allied species inhabiting Africa, but not found in St. Helena, and that the St. Helena species, till now unnamed, is distinct (*Aegialites sanctæ helenæ*, Harting). Vieillot's name, *Ch. varius*, must also take precedence of Temminck's *Ch. pecuarius*. An illustration is given of each of the birds referred to.—Messrs. Salvin and Elliot, in continuation of their notes on the *Trochilidæ*, discuss the genera *Pygmornis*, *Glaucis*, and *Threnetes*, separating the first into three groups, from the second removing *G. dohrni* to the genus Grypus, as already suspected by Mr. Gould, and adding *Glaucis ruckeri* to the third. The same ornithologists help to clear the synonomy of *Lophornis gouldi* by naming *L. reginæ* of Gould, *L. strictolophus*.—Mr T. Ayres continues his notes on birds in the republic of Trans-Vaal, and Mr. G. N. Lawrence on the Cuckoos of the genus *Neomorphus* defines precisely *N. geoffroyi*, *N. salvini*, *N. rufipennis*, and *N. pucherani*, showing that the specific validity of the last-named has been questioned by several distinguished ornithologists; though some time ago, Mr. Sclater, on seeing the type-specimen, was convinced of its being an excellent species.—Mr. Salvin figures the typical specimen of *Fulica alba* of White, showing that it is evidently of the genus *Notornis*, as pointed out by Herr von Pelzeln.—The Viscount Walden, P.Z.S., describes, as the last paper, a collection of birds from the Andaman Islands, made by Lieut. R. W. Ramsay; figuring *Centrococcyx andamanensis*, *Kittacincla albiventris*, *Sturnia andamanensis* and *Janthœnas columboides*, also entering into detail with reference to *Spilornis elgini*.

SOCIETIES AND ACADEMIES

Riga

Society of Naturalists, March 5.—Dr. Petzholdt concluded a series of five lectures on Turkestan, having described the fauna and flora, ethnographical features, dwellings, manners and customs, state of agriculture, mining and manufacture, &c. He commends the mode of treating silkworms as superior to that in Europe, and thinks the system of irrigation more perfect than in any other land not having scientific appliances. The Russian portion of Tasckkent, it is stated, has now a good chemical laboratory.

The *Correspondenzblatt* (No. 6) contains a note on uncommon forms of hair-growth, with reference to two Russian peasants exhibited before the Society in December.

March 19.—Herr Berg gave an account of his excursion to Kurland, and the plants and mollusca he met with.

March 26.—Dr. Nauck described an electrical experiment. A funnel with leather bag at the end is placed in a long glass cylinder, and has mercury poured into it. The liquid streams through the pores against the glass sides, and runs down. The lower part of the cylinder and the mercury in it are found positively electric, while the upper part and the funnel with its mercury are negative. The limit between positive and negative, after some variation, divides the cylinder into two parts, of which the lower is double the upper.

April 2.—Dr. Schell reported on the present arrangement of the meteorological station of Riga, and on observations of the water-mark at Riga and at Duna mouth in 1872.

BOOKS RECEIVED

Foreign.—Remarks on Synonyms of European Spiders: Prof T. Thorell (Upsala).—Lehrbuch der Physik, Dritte Lieferung: Dr. Paul Reis (Leipzig).

English.—Gateway to the Polynia, a Voyage to Spitzbergen, from the Journal of J. C. Wells, R.N (H. S. King & Co.).—Sound and Music: Sedley Taylor, M.A. (Macmillan & Co.)—Echoes from distant Footfalls: Rev. J. Boyes (Hodder & Stoughton).—Man a special Creation: William Sharpe, M.D. (R. Hardwicke).—Introduction to Physical Measurements: Dr. F. Hohlrausch (J. & A. Churchill).—Mitchell's Manual of Practical Assaying; Edited by Wm. Crookes (Longmans & Co.).—Descriptive Sociology, Classified and arranged by Herbert Spencer (Williams & Norgate).—Introductory Text Book of Geology: David Page, LL.D. (W. Blackwood & Sons).—Advanced Text Book of Physical Geography: David Page, LL.D. (W. Blackwood & Sons).—Half-hours in the Green Lanes: J. E. Taylor, F.Z.S (R. Hardwicke).—The African Sketch Book: Winwood Reade (Smith, Elder & Co.).—Lacerda's Journey to Cazembe in 1798, Translated by Capt. R. F. Burton (J. Murray).—Elements of Mineralogy: James Nicol, F.R.S.E (A. & C. Black).—Harveian Oration, 1873: G. Rolleston, M.D., F.R.S. (Macmillan & Co.).—Researches in Zoology, 2nd edition: John Blackwall, F.L.S. (J. Van Voorst).

CONTENTS

THURSDAY, SEPTEMBER 4, 1873

THE TESTIMONIAL TO MR. COLE

AS was to be expected, the subscriptions for the well-deserved testimonial to Mr. Cole, to which we have already referred, have so far been thorongbly satisfactory, upwards of 2,000*l.* having already been subscribed. Among the names of the subscribers will be noticed the names of men eminent in nearly every department of human activity. Thus we see Dr. De La Rue, Mr. Brassey, Mr. Baines, M.P., Messrs. Clowes and Son, Elkington and Co., Prof. Ella, Mr. C. J. Freake, Lord Ronald L. Gower, Sir Francis Grant, Earl Granville, Messrs. S. C. Hall, Hawkshaw, Hawksley, Lord Houghton, Messrs. H. A. Hunt, C.B., Jackson and Graham, John Kelk, Longmans, J. E. Millais, Lord C. Paget, Sir A. de Rothschild, Sir Titus Salt, Duke of Sutherland, Messrs. G. Trollope and Sons, Sir Richard Wallace, Dr. J. F. Watson, Marquis of Westminster, Sir Joseph Whitworth, &c. &c. We may well hope that ere the list be closed many more names will be added, and such a sum subscribed as will render possible a testimonial worthy of the services performed by Mr. Cole to all the best interests of this country.

The earliest work which can be considered to have a connection with Science undertaken by Mr. Cole, was the reform of the Patent Laws, which he advocated in 1850, afterwards inducing the Society of Arts to take up the subject. He wrote three Reports, and the principles which he laid down have been generally adopted as the basis of the present law. He particularly insisted upon the principle of a moderate fee at the first registration of an invention, such payment to increase at the option of the inventor in after years. He denounced all "taxes on inventions," as such, and public opinion is now beginning to go with him. Successive Governments have received hundreds of thousands of pounds from this source, and still withhold all proper aid to the encouragement of Science. There is a spice of sarcasm in the adage which has been worked in Sgraffito on the back wall of the new Science Schools, "Scientia non habet inimicum nisi ignorantem."

In 1852 Mr. Cole reformed, or we may almost say, established, the system of Art Schools, making it possible for every locality to have its Art School if it pleased. In 1853 the Department of Art was made Department of Science and Art, and Dr. Playfair was appointed to organise the Science division; but he shortly afterwards resigned his post, and became Professor of Chemistry at Edinburgh. Mr. Cole then became sole Secretary for Science and Art. The late Marquis of Salisbury was the Lord President, and doubtless to the great interest which this nobleman took in all matters appertaining to Science is to be ascribed some of the success with which Mr. Lowe was enabled to ventilate and carry out his views. Captain Donnelly, R.E., was invited to enter the Department, and through the instrumentality of Lord Salisbury, Mr. Cole, and Captain Donnelly the present Government system of scientific instruction throughout the country, one of the things of which England has the greatest reason to be proud, was evolved; and through the admirable harmony existing between Major Donnelly and Mr. Cole the work has been brought to its present flourishing condition. In 1856 there were 16 Science schools, in 1872 there were 1,238. This is one part of the work which Mr. Cole has done fo English Science, and we blush to think that it has not been appreciated by men of Science as it ought to be and as it will be appreciated.

The Report which has just been issued by the Science and Art Department as to the attendance in the various classes connected with it, and the number of visitors to the various museums during 1872, will give some idea of the magnitude of the work accomplished by Mr. Cole.

The number of persons who have during the year 1872 attended the Schools and classes of Science and Art in connection with the Science and Art Department is as follows: viz. 36,783 attending Science Schools and Classes in 1872, as against 38,015 in 1871, and 244,134 receiving instruction in Art, showing an increase on the previous year of 31,633, or nearly 15 per cent. At the Royal School of Mines there were 20 regular and 148 occasional, students; at the Royal College of Chemistry, 212 students; at the Metallurgical Laboratory, 30; at the Royal School of Naval Architecture there were 35. At the Royal College of Science for Ireland there were 20 associate or regular students, and 19 occasional students. The lectures delivered in the lecture theatre of the South Kensington Museum were attended by 11,958 persons, or 2,927 more than in 1871. The evening lectures to working men at the Royal School of Mines were attended by 2,400 persons; and 186 Science teachers attended the special course of lectures provided for their instruction in the new Science Schools at South Kensington. The various courses of lectures delivered in connection with the Department in Dublin were attended by 2,577 persons; and at the evening popular lectures, which were given in the Edinburgh Museum of Science and Art during the Session of 1871-2, there was an attendance of 1,416. The total number of persons, therefore, who received direct instruction as students, or by means of lectures, in connection with the Science and Art Department in 1872, is nearly 299,000, showing an increase as compared with the number in the previous year of 28,000 or 10 per cent. The museums and collections under the superintendence of the Department in London, Dublin, and Edinburgh, were last year visited by upwards of 2,922,000 persons, showing the very considerable increase of 1,141,000, or about 63 per cent. on the number in 1871. The returns received of the number of visitors at the Local Art and Industrial Exhibitions, to which objects were contributed from the South Kensington Museum, show an attendance of upwards of 574,000. The total number of separate attendances during the year 1872, as shown by the returns of the different Institutions and Exhibitions, in connection with the Department, has been upwards of 3,795,000. This total, compared with that of the previous year, presents an increase of 1,117,000, or 53 per cent., not including the number of visitors at local exhibitions, which was exceptionally augmented last year by the attendance of 420,000 at the Dublin Exhibition of Art and Industry, and is necessarily liable to much fluctuation from year to year.

We regret extremely to see that part of the great work done by Mr. Cole, in establishing the South Ken-

sington Museum, runs some risk of being undone by the unintelligent intermeddling of Government. It would appear from statements recently made in the House of Commons that arrangements were being made for transferring the management of the South Kensington, Bethnal Green, and similar institutions to the trustees of the British Museum. It is difficult for an outsider to see what Government means by contemplating such a step; we believe no better means could be taken to cripple the efficiency of such institutions than by giving them over to the irresponsible management of the unpaid trustees of the British Museum, who have at present much work on their hands, which is the subject of constant Parliamentary inquiry. We cannot conceive that Mr. Cole would approve of any such step, a step which, we repeat, would be sure to mar the great work which, with untiring labour, all-conquering zeal, and advanced intelligence, he has accomplished. Report indeed has reached us that a National Committee is being formed to urge upon Mr. Gladstone's re-constituted Government the necessity of putting the British Museum, the National Gallery, and Institutions supported by Parliamentary funds, and now Trustee-muddled, under the direct control of a responsible Minister.

Sir Joseph Whitworth consulted Mr. Cole upon the establishment of Scholarships for Mechanical Science, to take place after his death. Mr. Cole recommended him to establish them during his life, so that he might have the enjoyment of watching the progress of them. Sir Joseph followed this recommendation, and presented the country with 3,000*l.* a year for these Scholarships.

Mr. Cole is now devoting special attention to the application of Science to Productive Industry in the yearly International Exhibitions, and we trust that he may long be spared to reap the honour which is his due and to help on the work of which he has laid the foundation.

The erection in Exhibition Road of the handsome Science Schools, one of the few buildings devoted to Science of which the country may be justly proud, which Mr. Cole has at length successfully achieved, is due solely to the persistency of his efforts, rendered more and more pertinacious by the obstinacy and penuriousness of the Treasury, which in the most niggardly spirit is still starving the work and preventing its proper development, simply because, we presume, it is a scientific work; and it was the intention of the recent Chancellor, Mr. Lowe, that in this particular England should be distanced by the smallest Continental or American state. It is fair to add that Mr. Cole was supported in this particular direction by the Duke of Buckingham, the Duke of Marlborough, and the Marquis of Ripon, who have successively been Lord Presidents since 1866.

ADVANCED TEXT-BOOK OF PHYSICAL GEOGRAPHY

Advanced Text-Book of Physical Geography. By David Page, LL.D., F.G.S., Professor of Geology in the College of Physical Science, Newcastle. Second and Enlarged Ed. (Edinburgh and London: Blackwood, 1873.)

PHYSICAL Geography is one of those branches of knowledge which, without being a science in itself, makes use of many of the Sciences to explain and illustrate the facts and phenomena with which it deals. So far as it is confined to the mere knowledge of facts and description of natural phenomena, no special acquaintance with any science is required; but when it comes to deal with the causes of phenomena and the deductions from geographical facts, it is essential that the teacher should himself possess a good general knowledge of several branches of modern Science. In particular it is necessary that he should clearly grasp the main principles of Physics, that he should have a good acquaintance with the distribution of animals and plants, and so much familiarity with arithmetic and mathematics as to be able to avoid making statements which are palpably incorrect.

After a careful examination of the present volume, we are forced to conclude that the author is, on all the above-mentioned points, unfitted to teach this particular subject. It is with much regret that we say this, having expected something very different, not only from the popularity of Prof. Page as an author and a teacher, but also from the criticism of one of our first literary periodicals (used as an advertisement), that the work is "a thoroughly good text-book of Physical Geography." In order to justify this difference of opinion from so high an authority, it will be necessary to point out what are the most prominent errors and defects in the volume. Some of these defects may, it is true, be mere oversights; but most persons will be of opinion that, in the second edition of an educational work, the plea of "oversight" can hardly be allowed.

In the second chapter — on the figure, motion, and dimensions of the earth—we find a series of curious misconceptions, blunders, or obscurities. At page 19 we have the globe "revolving and rotating in obedience to the laws of gravitation and attraction," and in the next page these words are again used as implying distinct "forces." On page 21 occurs the following:—"But day and night are of unequal and varying length according to the *seasons;* and these seasonal successions are caused by the facts—first, that the orbit or path of the earth's revolution round the sun is not a perfect circle, but an ellipse; and second, that in performing this revolution her axis is not perpendicular, but inclined at an angle of 66° 27½′ to the plane of her orbit." This is simply absurd. The ellipticity of the earth's orbit has nothing whatever to do with the fact of there being seasons, which would occur exactly the same were the orbit a perfect circle. The actual effect of the elliptic orbit in slightly modifying the length and severity of winter in the two hemispheres, and which is of some importance as being an element in explanation of the cause of the glacial epoch, is never so much as alluded to. In a recent public examination some of the competitors gave this very account of the seasons, and received few or no marks in consequence. They had probably got up the subject from Dr. Page's volume. Three pages further we have a table of certain dimensions of the planets. This has no particular bearing on physical geography, but as it is given it should have been correct. It is, however, full of gross blunders, which can be detected by observation alone. We have in three columns—the diameter in miles, the cubic contents in miles, and the volume, earth being taken as 1. Now the "solid contents" and the "volume" being the same

dimension expressed in different ways, must be proportionate in any two planets; yet we have Mercury, volume 0·06, solid contents 10·195; Venus, volume 0·96, solid contents 223·521, so that while the volume of Venus is 16 times that of Mercury, its solid content is 22 times! Again: Earth, volume 1·00, solid content 260·775; Mars, volume 0·14, solid content 48·723, the earth being over 7 times the volume of Mars, but only $5\frac{1}{2}$ times its solid content. Almost any other two planets come out equally wrong. Again, from the diameters given the solid contents can be easily calculated, but here again is frequent error; and to add to the confusion, in at least two cases the diameters are seriously wrong (4,980 miles instead of 4,100 for Mars, for instance), so that it is very difficult to understand where so many mistakes could have come from. On the next page we have a contradiction as to the earth's internal structure. It is first stated positively that "the interior of the earth cannot be composed of the same materials that constitute its outer portion," and lower down, that "either the interior of the earth is composed of materials differing altogether from those known at the surface, or the compression must be counteracted," &c. At page 27 we have the atmosphere described as "mainly composed of two gases, nitrogen and oxygen—79 parts of the former to 21 of the latter—with a small percentage of carbonic acid and other extraneous impurities." Considering the importance of the carbonic acid gas in the atmosphere, it is hardly instructive to class it as an "extraneous impurity."

Passing over the mere description of the earth's surface, parts of which are very well done, we find other objectionable matter as soon as we have to deal with the explanation of phenomena. A mountain range is said at p. 75 to be "not a simple upheaval, the result of one paroxysmal outburst, but the work of innumerable volcanoes and earthquakes operating through ages and subsequently escarped and chiselled by rains, frosts," &c. Here gradual elevation without volcanoes or earthquakes, and possibly from altogether different causes, is ignored. On the next page, speaking of circumdenudation, we have:—"A mountain may thus consist of stratified rocks and be wholly unconnected with any forces of upheaval or ejection from below." Here ignoring that the strata must be upheaved before they can be circumdenuded. These are perhaps slight matters, but we think an introductory work should not adduce the almost exploded theory of Elie de Beaumont on the parallelism of mountain chains of the same age, "even when in opposite hemispheres," as if it were generally admitted, or Prof. Hopkins' explanation of central mountains with diverging spurs as the result of an upheaving force acting on a point, without stating that a very different explanation of the facts is adopted by most modern geologists.

When we come to the subject of the ocean, involving many nice problems in physics, our author is again altogether at fault. It seems hardly credible that he should not know the difference between salt and fresh water as regards the point of maximum density, on which much of the theory of oceanic circulation and temperature depends; yet such seems to be the case. At p. 123 we are told that "at 40° Fahr. water is at its minimum volume and maximum density," and again in the same page—"Its maximum density or minimum volume at $39\frac{1}{2}$, its expansion as ice to one-ninth of its bulk at 32° for fresh water and at $28\frac{1}{4}$ or less for salt water." Again, at p. 131 we have—"As already mentioned, water acquires its minimum volume or greatest density at a temperature of 40°, and becomes lighter as it rises above or falls below this temperature. Owing to this property a perpetual interchange or circulation is kept up among the waters of the ocean," proving that sea-water also is supposed by the writer to have this property, instead of increasing in density down to about $27\frac{1}{2}$°, as it actually does. Yet the author quotes Maury, who published this correction of the old notion in 1861, and the papers of Dr. Carpenter, who repeatedly refers to this fact as a most important one. Again, at p. 136 we have the obsolete theory of Sir James Ross as to deep-sea temperatures given in full, with a remark that it has recently "been materially interfered with" by the experiment of Drs. Carpenter and Wyville Thomson; but without, apparently, any acquaintance with the whole of the facts established by those gentlemen, as shown by again referring to the temperature of the bottom of the ocean as being 39° Fahr., "that of its maximum density."

It is perhaps a small matter that, in describing the Nile valley, Capt. Speke's account is quoted at length (p. 181), and the Victoria Nyanza given as the source, the Albert Nyanza not being once mentioned, or any allusion whatever made to the fact that Sir Samuel Baker claims it to be the true source of the Nile; but it is of great importance that the student should be impressed with clear and accurate ideas as to the cause of winds. Yet we find here the old school-book notion of a vaccum and an inrush to fill it up. "As air is expanded by heat and contracted by cold the warmer and lighter volumes will ascend, and the colder and denser rush in from all sides to supply the vacancy" (p. 205). "The air of the torrid zone becomes rarefied and ascends, while the colder and denser air sets in from either side to supply the deficiency" (p. 213). And the same words are repeated at p. 243. But every physicist knows that there is no "vacancy" and no "deficiency" in the case, but merely a disturbance of equilibrium; and unless this is clearly comprehended the causes and effects of atmospheric currents can never be understood. On the subject of light and heat the ideas of the author appear to be still more confused. At p. 205 he says—"As the atmosphere is the medium through which the sun's heat is conveyed to and disseminated over the earth, so also it is the medium of his light-giving rays." This sentence will certainly convey to the learner the false notion that the atmosphere is in some way essential to the "conveyance" of light and heat from the sun to the earth; and this is further dilated upon in the following vague and unintelligible, if not erroneous sentence:—"Heat and light are alike indispensable to plants and animals, and, from the peculiar constitution of the atmosphere, as regards its varying density, moisture, &c., both are reflected and diffused so as to become most available to vegetable and animal life." The learner must be very acute who can obtain any definite information from such oracular teaching as this. Again (at p. 207) we have a total misconception as to the cause of the decrease of temperature at increasing elevations—"The heat that falls on the land being partly absorbed and partly radiated into the atmo-

sphere, the lowest aërial strata or those nearest the influence of this radiation will be warmer than those at higher elevations." But it is a thoroughly well established fact that the atmosphere is scarcely at all warmed by radiant heat, except when charged with vapour, but almost wholly by contact with the heated earth, and that the diminution of temperature upwards is due to the cooling by expansion of the air which rises from below, and to its greater diathermacy, owing to the comparatively small amount of vapour at great elevations. In the whole of this part of the book there is no allusion to the effect of atmospheric vapour in checking radiation, so that the learner is left without a clue to the comprehension of some of the most important and interesting facts in climatology.

The latter division of the volume treats of the distribution of life, but it deals chiefly in vague generalities, and shows little acquaintance with the large amount of research which has of late years been bestowed on this subject. The distribution of plants is illustrated by means of the eight zones, from equatorial to polar; and there is no hint to the student that this is not a natural system or that there are any other causes than climate, soil, and altitude that determine the flora of a region. Here, too, we are not free from absurd errors, such as rhododendron and azalea being given as characteristic of the "American Arctic zone," while "box, saxifrage, and gum" (!) are said to grow up to 4,200 ft. on the Pyrenees, and "rice and wheat" in "those provinces subject to the influence of tropical seasons!" (p. 257). Animal life is treated in an equally loose and obsolete fashion. We find such terms as "homoiozoic zones" and "latitudinal distribution" repeated *ad nauseam*, but in illustration of these the student is told that the opossum is peculiar to the north temperate zone, and the kangaroo to the southern, apparently in complete ignorance that opossums abound all through tropical South America, while kangaroos inhabit tropical Australia and equatorial New Guinea, as well as the more temperate regions. "The eagle and falcon" are also given as peculiar to the temperate zone, while "the wolf" is said to be peculiarly arctic (p. 261). We are next informed that—"it has been attempted to arrange the earth's surface into certain zoological kingdoms and provinces, but it must be confessed with much less precision and certainty than in the case of the vegetable world"—which is exactly the reverse of the fact,—and then we have the now obsolete arrangement of Edward Forbes put forth, without a word about the labours of Sclater, Günther, Murray, Blyth, Blandford, Huxley, and others, who have established what all agree are natural zoological divisions of the earth (which has not yet been done in botany), although they may still differ as to the comparative rank of those divisions. We are not therefore much surprised when (at p. 263) we are told that in the Moluccas and Timor "there is a great abundance of carnivora and other orders of animals (!)' or that we have (at p. 269) the entirely novel assertion that "on the introduction of some new exotic, animals hitherto unknown in that locality usually make their appearance." Having perhaps read or heard of Mr. Darwin's celebrated case of the heartsease, bees, mice, and cats ("Origin of Species," 6th ed., p. 57), Dr. Page holds forth as follows:—"Certain birds, for example, feed on certain insects, and these insects again find their chosen food in certain plants; remove the plants and you destroy the insects, and by the destruction of the insects you compel the birds to remove and find othe habitats, or if these supplies cannot be found the birds are extirpated." Mr. Darwin gives a possible and very probable case founded on careful observation, but here we have a very improbable, if not impossible case, founded on imagination; because no birds feed on "certain"—that is definite species of—insects only, and comparatively few insects again are restricted to certain definite species of plants, so that there is no reason to believe that any insectivorous bird could ever be extirpated, or even rendered scarce, by the destruction of a single species of plant with the insects that feed upon it.

Next we come to the subject of mankind with the inevitable five races of Blumenbach, no notice whatever being taken of more modern classifications. Thus, the hill-tribes of India are left with the Caucasians, and the New Zealanders, Papuans, Australians, and Malays, are all jumbled together as forming one race. In the concluding chapter, which is a kind of summary of the whole work, we find it stated that the new world is characterised by more "uniformity of vegetable and animal life" than Europe, the exact contrary being the case; that "the vegetation of Africa is much less varied than that of Europe or Asia," which is equally untrue as regards Europe; the Cape of Good Hope alone equalling it in the number of families and genera of plants, while the difference between its northern and southern extremities is far greater than any corresponding difference in Europe; and, that the Polynesians are "utterly uncivilised." Having now gone through the book, we find that several classes of earth-knowledge have been totally omitted. The great subjects of terrestrial magnetism and atmospheric electricity are altogether ignored, while such phenomena as the rainbow, the blue sky, and meteoric stones, are never once mentioned.

The great and radical defects which have now been pointed out are not however the only ones, although they are by far the most important. The work is carelessly written, and the author seems not to have thought it worth while, even in a second edition, to correct errors, erase repetitions, or make sentences intelligible. A passage is repeated word for word about the middle and near the bottom of p. 27. "Contour" and "vertical relief" are defined in almost the same words three times over at pp. 62, 66 and 72. The two first lines on p. 21 are unintelligible, owing to some omitted words; and the second line of p. 28 is palpably ungrammatical. These, however, are small matters, and would not have been noticed had the author carried out with any approach to completeness and accuracy his somewhat lofty pretensions. He tells us that it is his object to "present an outline of the science in its higher bearings," to rise above mere external appearances, and seek to explain the causes that produce them, and that "he has endeavoured to embrace all that is important in recent discovery and hypothesis." The numerous quotations and references now given will enable the reader to judge how far the opinion expressed at the commencement of this article is well founded, and, if they agree with that opinion, they will feel some indignation that periodicals of high standing should (through ignorance or something worse), mislead the public so far as to tell them that this is "a thoroughly good text-book of Physical Geography." (!) This is the more to be

regretted, as there are two well-known works to which the epithet is fairly applicable, and which are at least free from such erroneous facts and false or exploded theories as have been pointed out in Dr. Page's volume.

ALFRED R. WALLACE

OUR BOOK SHELF

Half-hours in the Green Lanes: a Book for a Country Stroll. By J. E. Taylor. (Hardwicke.)

THERE are two ways at least in which the first principles of Natural Science may be taught to the youthful mind, as well as to "intelligent people who have not had time to enter into the technicalities of scientific questions." One which, if we may judge from the number of elementary works on Physics in which it is adopted, has many arguments in its favour, consists in the careful and logical working out in detail of a few of the most important principles of the Science, together with the different steps by which they were arrived at; the knowledge of minutiæ being left for future observation and study, on the foundation supplied: and the other is little more than a compilation of disconnected facts, of unequal importance, arranged with an endeavour to make them impressive from their almost endless number, and strung together with teleological argument. The tenants of the "tarns and green lanes being the objects treated of, there is an expanded field for the 300 or so short pages, in which the fishes, molluscs, and reptiles of the former, as well as the birds, insects, and plants of the latter, are rapidly passed in review. Several excellent figures illustrate the work, Mr. Wood and Mr. Keulemans contributing to the ornithological section; however, we are surprised to see so many on subjects of comparatively little importance, as the 14 on the slight variations in the shape and marking of cycloid scales, and the 32 on the different species of snails. Turning to the letterpress, many of the descriptions will be found to be accurate and clear, and a few sufficiently long to enable the uninitiated to form a fair idea of the subject. Many however are so short and incomplete that but little can be made of them without extraneous assistance, and in some the carelessness in the choice of words adds to the difficulty, as where the Vapourer Moth (*Orgyia antiqua*) is said to derive its name "from the habit of the winged males rising and falling simultaneously in their flight." A fact is sometimes stretched to make a *simile*, as when we are inaccurately told that "the generic name of the Kingfisher (*Halcyon*) is derived from the ancient belief that when it was hatching its eggs, the water was always calm and still." The genus *Turdus* is more than once called *Tardus*, and several other mistakes show that the author's knowledge of the subject is not of the deepest, as when the hind wing of the Clifden Nonpareil (*Catocala fraxini*) is said to be black and red, and the wide geographical distribution of the Kingfisher is given as a reason for supposing that it has a comparatively high geological antiquity. Notwithstanding its faults, however, there are many points in this small work which will make it of more than ordinary interest to the general reader.

The Royal Readers. Nos. 1 to 6. (Nelson and Sons. London and Edinburgh.)

THE excellence of these reading books and their adaptation to the broader culture of the present day demand from us some notice. The editor of the series, who has done his work with unusual ability, tells us in the preface that his aim has been to cultivate the *love* of reading. So far as we are able to judge, this aim he has successfully carried out by presenting interesting subjects in an attractive way. Opening any one of these Readers, we are struck with the air of freshness and interest it possesses. An intelligent child, instead of closing the book with relief, is far more likely to leave it with regret. And added to the happy way in which the lessons have been prepared, the pages abound with capital woodcuts, some of which are of real beauty. There are none of the stereotyped cuts of stale children in old-fashioned dresses and hair in pig-tails, primly grouped at play, and supposed to illustrate the story of the goody-goody girl, or the naughty-naughty boy. Our children are mercifully spared from these haunting ghosts of our childhood and have their Royal Readers instead. But these books have a wider scope than mere reading lessons. In the fifth and sixth books we find a large amount of sound scientific knowledge conveyed in a course of lessons carefully prepared by the editor. Then there are articles on physical geography, the bed of the sea, the various ocean routes, and lessons on useful inventions, besides some other novel features which we have not room to detail. The employment of these reading books will certainly tend to create a love for healthy reading, and at the same time they seem likely to be of the highest service in training and furnishing the minds of children.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.]

Atoms and Ether

I AM not enough of a metaphysician to say whether a substance which can be compressed and expanded *necessarily* contains void spaces.

If so, the idea of air, furnished to a beginner by instruction in "Boyle's Law," is self-contradictory; and any molecular theory afterwards developed in order to account for "Boyle's Law," may claim not only ingenuity but necessity in order to abate a crying grievance to all right-minded persons.

I do not myself believe in Prof. Challis's æther, but at the same time I do not believe in the power of the human mind to pronounce that a continuous medium capable of being compressed is an impossibility.

But, on the other hand, I am sure that a medium consisting of molecules is essentially viscous; that is, any motions on a large scale which exist in it are always being converted into molecular agitation, otherwise called heat, so that every molecular medium is the seat of the dissipation of energy, and is getting hotter at the expense of the motions which it transmits. Hence no perfect fluid can be molecular. So far as I can see, Prof. Challis intends his æther to be a perfect fluid, and therefore continuous (see p. 16 of his Essay), though he does not himself pronounce upon its intimate constitution.

Hansemann* makes his æther molecular, and in fact a gas with the molecules immensely diminished in size.

With regard to Mr. Mott's iron bar, when he pulls one end he diminishes, in some unknown way, the pressure between the particles of the iron, and allows the pressure of the æther on the other end to produce its effect.

N.B. This is only the language of a theory, and that theory not mine; nevertheless, I think it is consistent with itself.

Glenlair, Aug. 13 J. C. M.

Reflected Rainbows

I READ with great interest, in Prof. Tyndall's American lectures, a statement about the rainbow which appeared to me so extraordinary, that I determined to test it on the first opportunity.

The statement (I have not the book with me here, and give merely my recollection of the substance) is that, owing to the want of the necessary condition of parallelism the rays scattered from rain-drops cannot be so reflected as to show a rainbow by reflection from the surface of a lake.

Of course we all know that the same rainbow cannot be seen from two places at the same time, and therefore no one would

* Die Atome und ihre Bewegungen, von Gustav Hansemann. E. H Mayer: Coln, 1871.)

expect to see the *same* rainbow directly and by reflection. It is also reasonable to suppose that, as a rainbow is often seen from one place and not from another, a rainbow may often be seen directly and not reflected, or *vice versâ*. The reference to the necessary condition of parallelism shows that it is something more than these obvious deductions from the laws of reflection to which Prof. Tyndall wishes to draw attention in the passage mentioned. Until I tried the experiment described below, I imagined him to mean that there was something about the direction or arrangement of the rays of light producing a rainbow, which prevented their forming a rainbow or anything like one, after reflection from the surface of still water. It is not always easy to arrange so as to have a rainbow and a still lake to experiment upon. I managed, however, to get satisfactory substitutes in the spray bow at the falls of the Rhine near this, and a small pool of water. I was greatly disappointed on looking into my pool, to see reflected not only the scenery of the falls, but also a very fine spray bow.

What then can Prof. Tyndall mean? How is this peculiarity of rainbows to be observed? I have tried it in the only way of which I could think, but am now inclined to believe that I must have mistaken Prof. Tyndall's meaning.

Schaffhausen, Aug. 23 Z. X. Y.

The Origin of Nerve Force

ONE at least of the "obvious difficulties" which your correspondent, Mr. Henry R. Proctor, finds in my hypothesis as to the origin of Nerve Force, would scarcely have existed if he had directed his attention to a sentence in my article (NATURE, July 31), which runs thus: "In what are termed hot-blooded animals, that is, in mammals and birds, the difference of temperature between the surface and the interior is considerable under all natural circumstances, and in them there is a regulating action of the skin by which they maintain a uniform internal temperature, *always hotter than the surface*, whatever that of the external medium may be." The correctness of this proposition as regards the human being is now a physiological fact, as many observers from different starting points have arrived at the same conclusion; among others, my proof of it has appeared in the "Journal of Anatomy and Physiology" (vol. vi. November 1871). When the temperature of the atmosphere is above 70° F. the amount of perspiration is always proportionate to the temperature, and is sufficient to maintain the depths of the body at 98° or so. Below 70° the same condition results from the influence of cold on the cutaneous vessels, they contracting in proportion to the degree of cold, and so modifying the radiating and conducting power of the body surface. There is never therefore any reversal of the current, or a temperature at which it is *nil*.

Your correspondent's third paragraph contains an assumption, as great and not so reasonable as my own. Why should we have to assume that the body has to be kept at a constant temperature of 98° or so? There is no *a priori* reason in its favour. It may be said that the chemical changes which occur, being dependent on the properties of albumen, fibrin, &c., could not be continued under other circumstances. That, however, is only a shifting of the ground of argument, for it is much more reasonable to suppose that the properties of the animal tissues are the result and not the cause of the conditions under which they have been brought into existence.

I may mention that the physiological phenomena attending the immersion of the body in air and water of different temperatures are of quite a different character; they are scarcely comparable, and can be shown not to depend to any extent on the different conducting powers of the media, or their different specific heats. Immersion of the nude body in air of 30° is not rapidly fatal, even if the temperature is not kept up by violent exercise; and I cannot understand "immersion in water at 30°."

If the comparative coldness of the brain were the effect of absorption of heat in the building up of its elaborate texture, we should expect to find a similar condition in the muscles, which are also of very complicate construction. Such, however, is not the case, and therefore another explanation has to be found, which my hypothesis supplies.

Aug. 26 A. H. GARROD

The Flight of Birds

I HAVE just read with great interest, in NATURE of Aug. 21, Capt. J. Herschel's account (elicited by Mr. Guthrie's letter, vol. viii. p. 86) of his ocular and telescopic observations of Indian kites at rest in mid-air, and I am tempted to offer an explanation which occurs to me of the way in which that aërial balance may be maintained.

If there was no quiver of the wings perceptible "at an apparent distance of ten or twelve feet,"—if the very tips of the wings "looked as steady as those of a stuffed specimen,"—then certainly the theory of self-support by muscular action must be abandoned, and the problem is reduced to one in which we have only to consider the weight and shape of the bird with outspread wings and the velocity and direction of the wind.

If the direction of the wind is slanting upwards with moderate velocity, it is conceivable that a bird, facing the wind, with outspread wings in a plane inclined between the horizontal and the direction of the wind, might remain at rest, from the following considerations:—

If the air were at rest, the bird, with the plane of its wings inclined a little downwards and forwards, would not fall vertically, but would slide obliquely forwards down the air, like a returning boomerang, or an inclined sheet of paper let fall, and would reach the earth at some point far from the vertical. But suppose, instead of the air being at rest, there were a slant upward current of air meeting and balancing the slant fall of the bird: then the bird would remain motionless in mid-air.

Capt. Herschel rejects (perhaps too hastily) the notion of "slants of wind," and asks "what becomes of the horizontal force" of the wind. Surely its effect would be to balance the horizontally resolved portion of the bird's slant fall, just as the vertically resolved portion of the slant current of wind would balance the vertically resolved portion of the slant fall.

Different degrees of inclination and force of the wind might be met (within limits) by different degrees of slope and spread of the wings.

I must confess this is only theory. We want more observations, as keen and careful as Capt. Herschel's, to ascertain the force and direction of the wind attending this arrest of motion in mid-air. Slant currents are common enough on a small scale among house-walls, and on a larger scale we may see how the wind pounces down on a land-locked water, or presses up a mountain side. In a steady wind, the shapes of hill and valley must cause certain regular currents variously inclined to the horizontal, and some of these, I suppose, the eagles find and use. On the lee side of a hill (as in the case given by Captain Herschel) there would be a current rising from the eddy to join the main course of the wind. The conditions described by Mr. Guthrie were just such as would throw the wind into upward slanting currents.

We should want a well-balanced weather-cock with a double vane (one plate in a *horizontal*, the other in a vertical plane), to tell the *vertical* as well as the horizontal deviation of the wind.

Dacre Park, Lee, S.E., Aug. 24 HUBERT AIRY

Mallet-Palmieri's "Vesuvius"

MY absence in Spain during the months of March and April prevented my having seen NATURE for the 20th March, and left me until a few days since in blissful ignorance that it contained a lengthy critique by Mr. Mallet on my review (NATURE, Feb 6) of his translation of "Palmieri's "Incendio Vesuviano." This accounts for my silence, as, had it not been the case, a reply from me would certainly have appeared at the time.

For, being "the reviewer reviewed," I suppose I am indebted to my habit of not taking advantage of a reviewer's privilege, but of signing my name in full, since I do not find that Mr. Mallet vouchsafed a reply to any other review of his book, not even to that contained in the *Geological Magazine* for March, which, as the organ of British Geological opinion, might be expected to have the preference over mine, even if its reviewer had not incurred special claims on Mr. Mallet's attention, by having handled his production in a vastly less tender manner than I had done.

In comparing the two translations of Palmieri's little pamphlet, I give preference to that in German by the eminent mineral chemist Rammelsberg, if for no other reasons, for its cheapness, and because the translator puts forth the work of the Italian professor entirely on its own merits as one which did not require to be heralded by any elaborate preface to make it take with the public, and also because it seems somewhat unfair to see the worthy Professor's excellent observations made a vehicle for introducing the public to what, although entitled "an introduc-

tory sketch of the present state of our knowledge of terrestrial vulcanicity," &c., is far from being such, and in greater part but a one-sided exposition of Mr. Mallet's own views of what he terms vulcanicity and vulcanology, and which, to quote one of his reviewers, "has really no connection with Palmieri's report."

It is unnecessary here to occupy space in splitting hairs over the exact definition of words, such as theory, hypothesis, force, &c., being quite content to assume that the readers of NATURE fully understood the sense in which I employed them; but when the abstracts published in the "Proceedings of the Royal Society" are generally admitted to be faithful reports of the main features of the Memoirs read before the Society, and here it is not a question of details, I ask any rational individual whether Mr. Mallet, merely because he considers the abstract of his paper as "most meagre and incomplete," is justified in using such words (p. 382) as "Mr. Forbes commences with an important error as to a matter of fact, by referring to 'Mr. Mallet's Dynamical Theory of Volcanic Energy,' as published in the Proceedings of the Royal Society for 1872."

When an author commits himself to print, he should also be prepared for the consequences; yet the tone of Mr. Mallet's critique evidently indicates extreme irritation in finding his views commented upon before his communication to the Royal Society is published in full, explaining in other words, that before this is done nothing is known about them—a state of things eminently suggestive, both that the scientific men who, he is pleased to inform us, have already expressed themselves in his favour, may, after all, have been somewhat hasty in so doing, and also that Mr. Mallet would have been more wise if he had withheld his self-laudatory sketch until the publication of the evidence in favour of his views had afforded the scientific world the opportunity of forming a mature judgment as to their soundness.

Volcanic rocks, or rather rock species, are commonly arranged under the two classes, Trachytic and Pyroxenic, names proposed by Bunsen as the equivalents of acid and basic, and it is hardly necessary to observe that when the mineralogical and chemical natures of rocks are to be compared, some such classification must be taken into account, since it would be as absurd to liken a trachytic to a pyroxenic rock as chalk to cheese; it must also be remembered that the same volcanic cone may emit lavas of both these classes, a fact observed by the Scientific Commission at the eruption of Santorin, when in exactly similar manner to many ancient outbursts, the trachytic preceded the subsequent and more abundant pyroxenic lavas. As regards the mineralogical and chemical constitution of unaltered volcanic rocks, nothing is more certain than that from whatever part of the world they proceed, they are essentially made up of a very limited number of mineral species, always the same, and the application of the microscope to petrology has now proved this to be the case also, when they are of so compact a texture as not to admit of their constituent minerals being distinguished by the naked eye. The examination of any large collection of volcanic rocks cannot fail to impress the observer with the wonderful similarity of the various rock specimens from one volcano to corresponding ones from others situated at the greatest distances; and ample evidence of this may be seen in the writer's extensive collection, the result of many years' labours in the volcanic districts of Europe, America, Australasia, and Africa, and in which, for example, specimens may be seen of trachytes from Auvergne, the Rhine, or the Andes, undistinguishable from one another when placed side by side, other lavas from Otaheite (where, however, Pele's hair is not found, as mentioned by Mr. Mallet), to all appearance identical with those from Etna, both of which volcanic districts he has had good opportunities for studying.

Pele's hair, from Hawai, in the Sandwich Islands, so called from its having been blown by the action of the winds over the surface of the molten lava into hairlike filaments resembling spun glass, is simply pyroxene, a mineral which, next to felspar, is the most common constituent of the lavas of all volcanos.

When, however, Mr. Mallet asks, "Are the ancient basalts and trachytes identical with the modern ones or with each other in different localities?" the answer to the first question is simply no, for the results of modern petrological inquiry tend to show, although no sharp line can be drawn, that the volcanic rocks which made their appearance in the successive stages through which our globe has passed, although more or less characteristic of the epoch, were analogous to, but not absolutely identical with, those which either preceded or succeeded them; and to the second question the reply is, that they are identical in mineralogical and chemical constitution, and often even approximate closely in percentage composition.

The well-known researches of Bunsen on the volcanic rocks of Iceland, followed up by those of Abich on those of the Caucasus, showed the simplicity and identity in chemical constitution of volcanic rocks, and the later results of trustworthy chemical analyses, not of fragments chipped off at random, but of such as represent the mass of the unaltered rock itself, are every day bringing forward more complete evidence of this being the case; this is, without doubt, well understood by Professor Palmieri, for the very words cited by Mr. Mallet, in which he mentions that "two specimens of the same lava appear indeed to have their constituents in different proportions" are qualified by stating that the observatory did not possess the means of arriving "at any conclusion" on this point, and by expressing the hope that Prof. Fuchs, who had specially devoted himself to this subject, would, by employing "well selected and sufficiently large specimens," obtain satisfactory results. Not only do all chemists and mineralogists know that there may exist a considerable difference in the percentage composition of mineral species which are of identical chemical constitution, but in answer to Mr. Mallet's questions as to iron blast-furnace slags, every scientific metallurgist will admit that the basis of good smelting, necessitates the production of slags having a constant and definite chemical constitution, and that not only should the slag from every two tappings be identical in this respect, but that so long as the furnace works properly, and the same materials are charged into its mouth, the same slag will also flow from its hearth; many years' practical experience in the management of blast-furnaces, and the numerous analyses of slags which I have made, some of which will be found published as far back as 1846 in the British Association reports on the crystalline slags, have not only fully satisfied me on this point, but shown me examples of iron blast-furnaces, which, from their having been constantly fed with precisely the same ore, fuel, and flux, have not only for successive tappings, but for years, produced slags, not only identical in chemical constitution, but in which the percentage of the constituent silica and bases have only varied within extremely small limits.

When Mr. Mallet, however, asks such questions as whether the *crystalline* minerals of volcanic rocks are identical, and furnishes in his critique the most ample evidence of his confounding chemical constitution with percentage composition, ignoring altogether the laws of isomorphism and the substitution of bases, I believe mineralogists will absolve me from taking up more space in discussing further these questions. The implication of being unacquainted with the works of von Waltershausen, Senft, Blum, and my good friend Zirkel, which have been in my hands, I might almost say warm from the press, is easily disposed of, as numerous references will be found to them in my published papers; curiously enough, not long back I referred in a paper to opinions of von Waltershausen which are diametrically opposed to those held by Mr. Mallet; in the *Geological Magazine* for 1867, p. 227, references will be found to the other three works. If Mr. Mallet's knowledge of recent petrology is based upon "Blum's Handbuch der Lithologie," which he recommends "above all," I would remind him that this work, although a very excellent one when it was written in 1859, is now quite antiquated, this branch of mineralogica science being then, as it were, only in its cradle as compared to the great advances which have been made during the last eight or ten years: "von Waltershausen vulkanische Gesteine" appeared still earlier, in 1853.

I would remark that neither in this communication, nor in my review, was it the intention to take into consideration Mr. Mallet's theory of volcanic energy, and it was only alluded to because, in his Introductory sketch, he so altogether overlooked those explanations which, notwithstanding his reply, will still be demanded by chemists, mineralogists, and geologists, before they can accept his views; I still object most strongly to the tone and style of his introductory sketch, and I am not alone in doing so.

Thornton Cottage, Aug 8. DAVID FORBES

Explosion of Chlorine and Hydrogen

SOME time ago, being desirous of showing a class the explosion of chlorine and hydrogen by artificial light, I devised a simple method which was perfectly successful. Equal volumes of the two gases, prepared separately by the usual methods, were

mixed in a stout test tube and confined by a greased cork. This was placed upright on a little wooden stand, and kept in its place by a brass clip. About an inch of magnesium ribbon was suspended in a small tin shade by means of a wire clip. The magnesium being placed near the tube and lighted, the gases united with a report, jerking the cork to the ceiling, but in no case breaking the tube. W.

A NEW BUBALE, FROM ABYSSINIA

THE British Museum has just received a series of skins of a new Bubale from Abyssinia called Tora. It is like the Hartibeest for having a white patch on the rump, and white inside the ears, but it is without any black on the face or on the outer side of the limbs. It is of a bright pale bay colour, with black tuft on the tail, and the horns are much more slender than in the Hartibeest. I propose to call it *Alcephalus tora.*

J. E. GREY

FROM AMERICA TO ENGLAND BY BALLOON

THERE appears every likelihood that before the end of the year a feat will be attempted which seems to have been first seriously proposed thirty years ago by Prof. Wise, an American aëronaut, who is now making preparations to cross the Atlantic to England in a monster balloon. The American correspondent of the *Standard* has given full details of the elaborate construction of this balloon, and states the reasons which inspire Prof. Wise with unhesitating confidence that he will be able successfully to accomplish his aërial voyage.

The balloon, when completed, will be 160 ft. high, and the globe will be over 100 ft. in diameter. It will be able to lift from the ground, including its own weight, 14,000 pounds, and will have a net carrying capacity for passengers and ballast of 6,900 pounds. It will contain 600,000 cubic feet of illuminating gas, though only 400,000 feet will be put into it to allow for expansion in the higher regions of the atmosphere. The other details of construction are most elaborate, and every precaution seems to be taken to insure success and to provide for the safety of the four persons who are bold enough to risk their lives to gratify their curiosity and endeavour to increase the sum of human knowledge. The four voyagers will be Prof. Wise, Mr. Donaldson, an agent of the *Daily Graphic*, and a skilled mariner—for a copper-fastened cedar lifeboat, 22 ft. long and 4½ ft. beam, forms part of the appurtenances.

The hypothesis on which the enterprise is projected, is that there is a prevailing east-going current of air at an attainable elevation, in which a balloon can pass eastward from the American continent to Europe. The current is believed to be half-a-mile or more above the surface of the earth, and to move at the rate of from 50 to 150 miles an hour. It was a knowledge of this current that made Mr. Charles Green, the celebrated English aëronaut, say, in 1840, that he should start from America rather than from England to traverse the Atlantic in a balloon. The cause of the current is less definitely known than the fact. A French *savant* attributes it to "a decrease of participation in the rapidity of the rotary motion of the earth." Prof. Wise believes that this upper current of air, in the temperate zones, moves from west to east, because of the mingling of the south-west and north-west trade-winds in their circuits, in accordance with the laws of temperature and the aërial motion of the earth. The two currents, he believes, slide over each other, and the balloonist who knows his business can strike such a point as will carry him eastward, as it were, between them. That is to say, the zone lying between the 35th and 36th parallels is "a nodal zone," in which the south-west and north-west winds induce an intermediate current which moves nearly due east. In this highway the motion is about a hundred miles an hour.

The theory of the east-going current seems to be pretty well admitted. The direct experience which bears most strongly upon it is limited. There are three memorable balloon trips which are noteworthy. The current seems to set persistently eastward, deflected slightly towards the north by the rush of equatorial air towards the north. Prof. Wise, in 1859, in his trip from St. Louis to Jefferson county, in the State of New York, found the current almost due east; he travelled in balloon 1,156 miles in 19 hours. The speed here was only 61 miles an hour; but this can be accounted for. The great balloon voyage made by Nadar from Paris to Hanover was almost due eastward. This journey of 600 miles was made in about six hours—about a hundred miles an hour, although it was over the uneven surface of the Continent, diversified by hill, vale, stream, and so on. In the trip of Mr. Green, from London to Wellburg, in Nassau, the journey was about 600 miles, and was performed at the rate of about a hundred miles an hour, and there were the British Channel and other irregularities in the way of smooth sailing.

On the other hand, however, Mr. Glaisher in his experiments, in consequence of what Mr. Green had stated with regard to the constant prevalence of a current from the west, paid special attention to this point, and in his reports to the British Association in 1863 and 1864,* collected together the different directions in which the balloon had moved at different heights in his several ascents. From these it appears that the direction of the wind was quite as capricious at heights exceeding 5,000 ft. as it is on the surface of the earth. In Mr. Glaisher's winter ascents he did generally meet with a current from the south-west, certainly; but the number of such ascents was not great, and they were not to sufficient elevations to afford very trustworthy results. It is certain, however, that if there existed over England anything like a current of air constant in direction, it must have manifested itself distinctly in the course of Mr. Glaisher's thirty ascents, in all of which the direction of the wind at different elevations was a subject of careful observation.

Again, Prof. Newton of Yale College has written a letter to a recent number of the *Daily Graphic*, in which, from the observed behaviour of the luminous trains sometimes left by the brighter meteors at from forty to seventy miles high, he draws certain inferences which do not seem altogether favourable to Prof. Wise's theories. What these inferences are will be seen from the conclusion of his letter:—

"We have, then, at the *bottom* of the atmosphere, inconstant winds. We have just above us strata of air moving in diverse directions, for the lower clouds may move one way, the upper clouds another, while at the surface the winds may perhaps blow in a third. At two islands at short distances from each other we often have different winds.

"Again, we have for air near the top of the atmosphere, at least so high up that the density is exceedingly small, this fact, that lines (usually inclined to the horizon) only five or ten miles long almost always have their ends in air that is moving in different directions.

"Between the highest cloud and the lowest meteor trains lies an unknown region. It may be that here are uniform westerly winds. In the absence of direct observation neither this nor the contrary may be asserted. But it seems to me more rational to suppose that the complex system of currents at the bottom of the atmosphere is in direct connection with that at the top, and that there is a like complex system of currents and winds throughout the intermediate space. Of course, the general drifting of the air in the temperate zone to the east is unquestioned.

Prof. Joseph Henry, of the Smithsonian Institution,

* British Association Reports, 1863, p. 507, and 1864, p. 313.

who has had thirty years of observation in this direction, says :—

"'All the observations that have been made in the motions of the atmosphere, as well as the deductions from theoretical considerations, lead to the conclusion that the resultant motion of the air around the whole earth, within the temperate zones, especially about the middle of them, is from west to east.' Prof. Watson, the distinguished astronomer of the Michigan University, writes, 'I beg to say that there ought to be a strong current of air moving eastward in the upper regions, and that the experience of aëronauts goes to show that what the theory predicts actually exists. It seems to me quite possible to make an aërial voyage to Europe, and with great rapidity.' William H. Wahl, secretary of the Franklin Institute at Philadelphia, writes, 'I believe that, generally, Prof. Wise's proposition, concerning the existence of the elevated easterly current, is correct, and the same view is entertained upon theoretical grounds by meteorologists.' To the same effect writes Prof. Brocklesby, of Trinity College, author of 'Elements of Meteorology,' a work recognised as the best elementary text-book on the subject."

Still Prof. Henry is by no means enthusiastically in favour of seeing the dangerous voyage undertaken ; he speaks of it as at the best extremely hazardous, and would prefer that some one else in whom he is less interested than he is in Prof. Wise would undertake the risk. His letter to Mr. Wise, in which he thus speaks, is worth quoting for its meteorological value. He says—

"I have no doubt of the fact that, if your balloon can be sustained in the air sufficiently long, a voyage might be made across the Atlantic ; but this is the point which, it would appear to me, from my partial knowledge of what has been accomplished in the art of ballooning, is yet to be satisfactorily established. No one, however, has had more experience in the art than yourself, and you ought not to venture on the hazardous voyage without the fullest assurance that the balloon can be sustained at the requisite elevation for, say, ten days.

"I think it probable that over the ocean at a considerable elevation, the tendency to meet adverse currents will be less than over the land ; on the other hand, however, there will be a chance of meeting a cyclone, which might carry you around a circle of several thousand miles, and throw you back over the coast of the United States, since you would be most likely to meet the northern portion of the great whirl, which would be moving in the western direction, the only possible escape from which would be by ascending to a very high elevation. The higher temperature of the Gulf Stream tends to produce an ascent of air above it during the colder months of the year, but in summer this effect would scarcely be perceptible.

"Your remark in regard to the greater velocity of the easterly motion of the balloon at night is in accordance with meteorological principles, since at this period the unequal heating of the earth by the direct rays of the sun does not take place, and hence adverse currents are not as frequent. The cooling of the atmosphere in that part of the earth which is in the shadow will tend to produce at the surface of the earth, after sunset, a westerly current, while at a certain elevation above the earth, the current would at the same time be in an opposite direction. In the morning, just before and after sunrise, the current at the surface of the earth, produced by the cooling, would be eastward, while that in the atmosphere above would be westward."

There can be no doubt that this daring expedition, whether it descends without mishap on the shores of Europe, or comes to grief in the middle of the Atlantic, will add something to our knowledge of the atmosphere ; but many will no doubt think that all the knowledge that will be acquired by this sensational and hazardous method might be acquired by safer and more ordinary methods. We certainly, with all our heart, wish the enterprise complete success ; but we think it very pertinent to refer to some remarks on the project in *La Nature* by the experienced balloonist, M. G. Tissandier. After referring to the theory of the easterly current in the atmosphere, M. Tissandier says, "We leave to the aëronaut all the responsibility of this hypothesis, which appears to us to be based upon vague conjectures ; we should have a little more confidence in the resources which he expects to find above the Gulf Stream. This warm river, which traverses the extent of the Atlantic, should draw along with it a current of air, which the aërial navigator might take advantage of.

"We do not doubt the good faith of the aëronaut, who has already proved himself to be possessed of boldness and courage, but we believe he has not maturely considered the problem he proposes to solve. To go from New York to England, the aëronaut must travel a space of about 5,500 kilometres. Suppose that exceptional good fortune favours him, that a favourable wind, of mean intensity, having a speed of ten metres per second, blew regularly from west to east, without deviation, he must necessarily sojourn in the atmosphere six or seven days at the least, since the distance traversed in twenty-four hours will be, according to our hypothesis, 864 kilometres. But can an aërostat, no matter how voluminous it may be, constructed under existing conditions, and notwithstanding its complete impermeability, remain in the atmosphere for seven days? To this we reply, with the utmost confidence, in the negative. In fact, when a balloon quits the earth, as it rises a part of the enclosed gas is at once expelled by the dilatation due to the diminished pressure of the atmosphere ; but the aërostat soon plunges into regions where the temperature is much lower than that of the strata of terrestrial air which it has left. The cold contracts the gas, the balloon loses its ascending power and descends. To maintain it at the level it has reached, it is necessary to diminish the weight, and the aëronaut throws out ballast. If he pass a first night at great altitude, it is certain that he will be thus obliged almost continually to lighten his craft. Next morning, as the sun rises, the bright burning rays heat the gas contained in the aërostat. The balloon, which had partly collapsed during the night, begins to fill out, the loose material stretches like the head of a drum, and it mounts into the higher regions of the atmosphere. It is now that the aëronaut will feel the want of a portion of the ballast he was obliged to cast away during the night. If the sun is hot, the balloon will rise so high that it will be necessary to moderate its ascent by letting off some of the gas. During the second night the reverse process takes place. This time the aëronaut has no longer the same resources as before ; the ballast, which is his life, is being continually exhausted. I willingly admit he may have sufficient for the second and even for the third night ; but will he have enough for the sixth and seventh night, if the differences of temperature of day and night are considerable, as is probable? The moment will soon come when the sacks of sand will be empty ; the balloon will descend without any means being able to hold it back. But instead of encountering a hospitable soil, it strikes against the crest of the waves. The anchor instead of biting, will plunge in vain in the waters ; if the wind is violent, in spite of their life-boat, the voyagers may be prepared for a most horrible fate. The aërostat will be piteously raised by the wind, and the terrified train will shoot from wave to wave over the surface of the ocean. Unusually clever will be the men carried along by such a force, if they could manage to find the means of detaching the life-boat."

It is certainly true that it would be very difficult to sustain a balloon at a considerable elevation for six days (if the height of the balloon is a matter of indifference, the guide rope as used by Green would be quite sufficient

to answer this purpose, even with an ordinary balloon), but we think the management of the balloon may be very well left to Prof. Wise, whose opinion on all practical points of aërostation is probably of more value than that of any other man living. Of all the persons who have devoted themselves professionally to ballooning as a source of income, Prof. Wise is certainly the ablest, and his work on Aëronautics shows him to be possessed of considerable scientific claims. The project could not, therefore, be in better hands; and considering the originality and boldness displayed by Prof. Wise in several of his very numerous ascents, there is every reason to believe that nothing will be left undone to bring it to a successful issue. In all the technical matters relating to the balloon, therefore, Prof. Wise may be well trusted to take the best course; and with regard to the meteorological questions involved by consulting not only American meteorologists but also Mr. Glaisher and other gentlemen who have studied the question of the winds in relation to aërostation, it is clear that he intends to leave no stone unturned to obtain the best information attainable, and, at all events, merit success.

MAYNE'S SIDEREAL DIAL

THIS instrument consists of two moveable circles, which may be made of brass or pasteboard, placed in a common watch-case. The lower and outer one shows the hours doubled up to XXIV., and divided into quarters. The upper one, which is also inner, shows the sixty minutes, 5, 10, &c. This circle is a narrow one, and works on the plain inmost rim of the lower one, so as to admit of the hours being seen outside the minutes.

Each circle being set to show at the top of the case, where the XII. of the watch comes, the "Sidereal Time at Mean Noon" (given in the Nautical Almanack for each day in the year), the watch is placed in the case, and will continue to show the sidereal time corresponding to mean time approximately for six hours, after which interval the minute circle should be *put on* one minute to ensure greater exactness.

This will be found a near enough approximation for the amateur observer, using an equatorial instrument, and this simple method will be found to save an infinite amount of trouble *in finding objects whose R.A. is recorded in a catalogue, to those who, like the inventor, are unprovided with a sidereal clock.*

Mr. Norman Lockyer has suggested as an improvement, the use of a watch with the *seconds'* hand in the centre; this would necessitate a third, and still inner circle for the sixty seconds, by which, indeed, subject to an hourly correction of, say ten seconds being *put on*, the dial would be rendered accurate enough for rough transit observations; and this circle and *seconds'* hand have been added to the original design in the woodcut, where the dial is set to V. (¾) 47·10, the Sidereal Time at Mean Noon for the 18th June, 1873, the hands of the watch representing IV. (½) 32·12, which gives the corresponding Sidereal Time X. 19·22 (or applying the last-named correction, say 45 seconds for 4½ hours), X. 20·7.

It is as well perhaps, though scarcely needful, to add (for no one would be likely to make a mistake of 12 hours) that as the dial in the Example also reads XVII. (¾) 47·10, and as the mean time by the watch may be A.M. or P.M., the observer should bear in mind which half of the 24 hours, both astronomical and mean, he is working in.

The third or *seconds* circle is not indispensable, as the seconds hand, even in the ordinary position, can be made to fulfil its object, by setting it at noon to the Sidereal Second on the meridian; thus, in the Example, it would be set to 10, instead of to Zero, when the dial is set at noon, the correction for the equivalent of the lapsed interval being applied subsequently as required. But this involves altering the watch, which is objectionable; the use of the third, or *seconds'* circle, is therefore recommended, for although the seconds' hand, as placed in most watches, would not actually *point* to the Sidereal second, it is easy to refer the *position* of the mean second to the corresponding part of the watch's face, where the third circle can be read off at once.

ASHTON MAYNE, Captain,
Bombay Staff Corps,
Care of Messrs. Henry S. King & Co.,
65, Cornhill, London, E.C.

ON THE SCIENCE OF WEIGHING AND MEASURING, AND THE STANDARDS OF WEIGHT AND MEASURE *

IV.

The Imperial Standard Yard

THE immediate superintendence of the construction of the new standard yard was entrusted, in the first instance, to Mr. Baily, who conducted all the preliminary investigations and experiments. After his death in August 1844, it was undertaken by Mr. Sheepshanks, by whom and under whose direction by far the largest proportion of the actual operations was carried out, and all the comparing operations of the several standards of length made, up to the period of his death in August 1855. By this time the work was so far completed that not a single additional comparison of line measures was required. The detailed account of the construction of the new standard yard, and its verified copies, was then undertaken by the Astronomer Royal, with the aid of the documents left by Mr. Baily and Mr. Sheepshanks; and the winding-up of the work of the Commission, and the distribution of the scientifically verified copies of the standards also devolved upon the Astronomer Royal, as the chairman. The magnitude of the operations may be estimated from the fact of the number of micrometer readings for all the comparisons exceeding two hundred thousand; and amongst the operations it was found necessary to construct an entirely new system of thermometers. It should not be forgotten that the scientific gentlemen who bestowed so much of their valuable time, attention, and labour, during several years upon the experiments and observations for the important object of the restoration of the national standard of length, declined to accept any pecuniary remuneration.

The length of the new standard yard was determined in a similar manner to the determination of the weight of the new standard pound, by taking the mean length of the most authoritative standards which constituted the best primary evidence of the lost standard yard.

This standard measure of length had been constructed by Bird, in 1760, under the directions of the Committee of the House of Commons on Weights and Measures, first appointed in 1758. Its length was taken from a similar yard which had been constructed by Bird in 1758.

Fig. 8.—Standard Winchester Bushel of Henry VII ½ size.

Each of these standard yards consisted of a solid brass bar 1·05 inch square in section, and 39·73 inches long. Near each end of the upper surface gold pins or studs 0·1 inch in diameter were inserted, and points or dots were marked upon the gold to determine the length of the yard. The comparing apparatus in use at that period consisted of a beam compass with two fine measuring points, which could be adjusted to the dots on the standard measures under comparison. But the result of numerous comparisons of this kind made from time to time previously to the destruction of the standard in 1834, had been to leave the edges of the holes indented and irregularly worn away, so that the original centre was very difficult to ascertain. Mr. Baily, who had made some comparisons with this standard yard in the early part of the year 1834, describes the holes as appearing, under a microscope, like the miniature crater of a volcano.

The length of the standard yard of 1758, had been based upon that of the then existing Exchequer standard yard, which had been constructed in the reign of Queen Elizabeth in 1588, and upon the length of the Royal Society's standard yard, constructed as a scientific standard measure in 1742. It had been determined, upon comparison, to agree as nearly as possible with these two authoritative measures of a yard.

The two standard bars of 1758 and 1760 were found amongst the ruins of the Houses of Parliament, but they were too much injured to indicate the measure of a yard which had been marked upon them.

Bird's standard yard of 1760 had been left in the custody of the clerk of the House of Commons, and no legal authority was given to it as a standard of length until the passing of the Act 5 Geo. IV. C. 74, in 1824, already referred to. Meanwhile, other scientific standards of length had been constructed which may now be noticed.

In 1785, the first geodesical operations were begun, upon which the Ordnance Survey of the United Kingdom has since been founded, by General Roy's measurement of the base on Hounslow Heath. The standard used in the first instance for that purpose was that known as General Roy's scale, 42 inches in length, and constructed by Mr. Bird. This scale was based, not on the legal Exchequer Standard, but upon the Royal Society's scale, with which the whole length of the first 36 inches of General Roy's scale was compared, this constituting the *Ordnance yard*. Two standard yards of superior construction, belonging to the Ordnance Department, were placed at the disposal of the Standards Commission.

* Continued from p. 329.

These were bars of iron, and line standards, the lines being marked on gold pins at mid-depth of the bar, notches being cut in it for that purpose. They had been compared with the imperial standard in 1834, and a statement of their comparison was published in 1847 in the account of the measurement of the base at Lough Foyle.

Towards the close of the century, some important scientific operations for the improvement of the standards were undertaken by Sir George Shuckburgh. In 1796, a new standard measure subdivided in fine lines, and since known as "Shuckburgh's scale," was constructed under his direction, by Mr. Troughton, together with a new comparing apparatus carrying micrometer microscropes. This is stated to have been the first occasion on which this mode of optical comparison was employed, being substituted for the beam compasses previously used. The Shuckburgh scale, which is now in the possession of the Royal Society, consists of a brass bar 67¾ inches long, 1·4 in. wide, and 0·42 in. thick. It is a scale of 5 feet, divided by lines into feet, inches, and tenths of inches, each inch being numbered. It was adopted by the Standards Commission of 1819 as the scientific standard of length, as distinguished from the legal standard of the Exchequer. The length of the yard was laid down on the Shuckburgh scale from Bird's standard, and it had also been accurately compared with each of the other standard yards previously mentioned, and their lengths had been transferred by beam compasses to the Shuckburgh bar.

In pursuance of the recommendation of the Royal Commission of Weights and Measures appointed in 1819, and of the Act of 1824, passed to carry their recommendations into effect, a new Exchequer standard yard for regulating commercial measures of length was constructed under Capt. Kater's superintendence. It was not, however, laid down from the legal standard yard, which, together with the legal standard pound, remained in the custody of the Clerk of the House of Commons, but from the length 1—36 in. of the Shuckburgh scale, which was considered by Capt. Kater to be identical with the imperial standard.

The official standard yard constructed for the Exchequer, under Capt. Kater's superintendence, in 1824, and intended for the verification of the local standard yards used by inspectors for comparing trade measures, consists of a slender brass rod with two wooden handles, as an auxiliary end measure, and a bed measure, being a bar of brass one inch square with rectangular steel terminations of the same width projecting above the surface of the bar. The distance between the interior faces of the steel terminations is intended to be equal to the length of the imperial yard. This yard bed and rod were used together from 1825 to 1870, for verifying all the local standard yards of similar though ruder construction. A standard yard, with the legal subdivisions marked upon it, and of improved construction, having a convenient comparing apparatus attached to it, has since been substituted, and is now used in the Standards Department.

Four other standard yards of more scientific character were also made under Capt. Kater's directions, and are now in the Standards Office. These bars of brass are of the same width and thickness as the Shuckburgh Scale, and have the length of the yard defined by fine points upon gold studs in the middle axis of the bar, the thickness of the bar being reduced at its extremities one-half with this object. All these standard yards were constructed by Dollond. By an ingenious contrivance the point at one end of the bar, not being placed exactly in the centre of the circular gold stud, was made susceptible of adjustment, by turning the stud round; and after final adjustment of each yard and repeated comparisons with the Shuckburgh Scale, no perceptible error could be detected in any of them. A similar standard measure made for the Royal Society in 1831 was considered by the Commission to be the most favourable type of Kater's yard.

Having thus described the principal standard yard measures then existing, we may return to the operations of the Standards Commission. For determining the true length of the new standard yard, a provisional standard yard was employed by Mr. Sheepshanks. This was a new brass bar, called by him "Brass 2," and was accurately compared by him with the standards deemed to be the most authoritative, and which had been *directly* compared with the lost standard, viz. Shuckburgh's scale, Kater's yard made for the Royal Society, and the two Ordnance yards. The results in terms of the lost imperial standard were as follows:—

	In.		
Brass bar 2	= 36·000084	by comparison with	Shuckburgh scale 0–36 in.
,,	= 36·000280	,,	,, 10–46 in.
,,	= 36·000229	,,	Kater's Yard of 1831.
,,	= 36·000303	,,	Ordnance Yard, No. 1.
,,	= 36·000275	,,	,, No. 2.
,,	= 36·000234	by mean of all.	

Mr. Sheepshanks preferred 36·00025, as being sufficiently near the truth, and in constructing the new standard, he assumed as the basis of his proceedings—

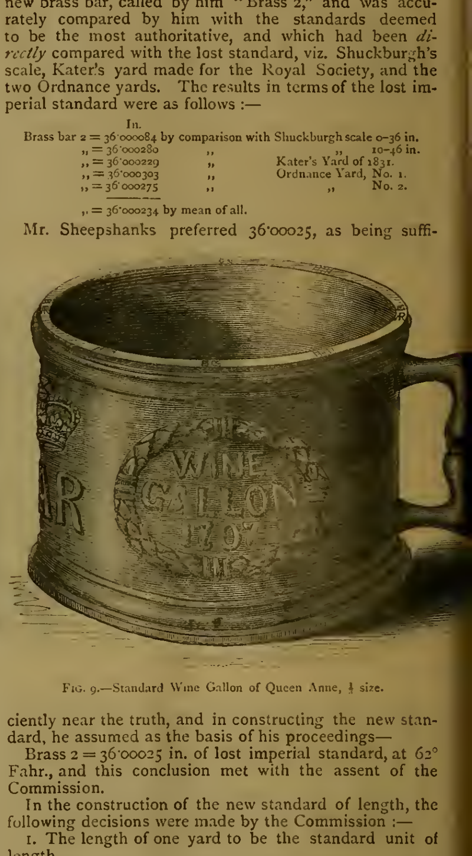

Fig. 9.—Standard Wine Gallon of Queen Anne, ¼ size.

Brass 2 = 36·00025 in. of lost imperial standard, at 62° Fahr., and this conclusion met with the assent of the Commission.

In the construction of the new standard of length, the following decisions were made by the Commission:—

1. The length of one yard to be the standard unit of length.

2. After considering whether the measure of length should be defined by the whole length of the bar, that is to say, an *end-standard*, or by the distance between either two points or two lines marked upon the bar, a *line-standard* was adopted in preference.

3. For the material of the bar, gun metal or bronze composed of

Copper	16 parts
Tin	2½ ,,
Zinc	1 ,,

was adopted after a series of experiments by Mr. Baily, and was recommended by him as containing the properties most essential for the construction of a standard intended to last through many ages, viz., almost perfect immunity from rust, with proved elasticity and rigidity.

The test bar of this alloy, when loaded at the centre with $5\frac{1}{2}$ cwt, broke without bending.

4. The form of the standard to be a solid bar 38 in. long, and 1 in. square in section. The measure of a yard to be defined by the distance between two fine lines perpendicular to the axis of the bar, marked upon gold studs at the bottom of cylindrical holes drilled from the upper surface to the mid-depth of the bar.

The gun-metal, or bronze, thus adopted for the new standard, has since been known as "Baily's metal," and this designation is engraved upon the Imperial standard yard.

In order to select the most perfect specimen for the new standard of length, 40 line-standard yards were constructed of Baily's metal, and one of these was finally selected as the Imperial standard, not only from its representing, with the greatest precision, the assumed length of the lost standard yard, but also from the clearness of its defining lines, and from its general good workmanship. Four of the remaining yards nearest in length to the new standard were selected as Parliamentary copies, and deposited in the same places as the Parliamentary copies of the standard pound already mentioned; and the rest were in like manner distributed amongst different countries and public institutions in this country.

Several other similar line-standard yards were also constructed for experimental purposes, being accurately verified by Mr. Sheepshanks, and were disposed of in like manner, viz

The defining terminations of these end-bars consist of a plug of agate, slightly conical and shrunk into a similar conical hole at each end of the middle axis of the bar. The ends of the bars are ground and polished in a spherical form, the centre of the spherical surface being the middle of the bar.

All the numerous comparisons of the standard yards were made by Mr. Sheepshanks in one of the lower cellars at Somerset House, under the apartments of the Royal Astronomical Society, where the new micrometrical comparing apparatus constructed for the purpose by Messrs. Troughton and Simms, was fixed.

A full description of the comparing apparatus will be given under head V. of Weighing and Measuring Instruments, and their Use.

The Commission for restoration of the standards having terminated their labours, recommended in their final report that the new imperial standards of the yard and pound be deposited at the Exchequer Office, there to be preserved under such regulations as to Parliament might appear fitting. In expressing their adherence to the recommendation of the Committee of 1841 that no reference should be made to natural elements for the values represented by the standards of weight and measure, they also recommended that so much of the Act 5 Geo. IV. c. 74, as provided for the restoration of the standards in the manner therein provided be repealed, and that the standards should in no way be defined by reference to any natural basis, such as the length of a degree of the meridian on the earth's surface in an assigned latitude, or the length of a pendulum vibrating seconds in a specified place. They considered the ascertaining of the earth's dimensions and the length of the seconds pendulum in terms of the standard of length, and the determination of the weight of a certain volume of water in terms of the standard of weight, as scientific problems of the highest importance, to the solution of which they trusted that Her Majesty's Government would always give their most liberal assistance, but they did not urge them on the Government as connected with the conservation of standards.

These recommendations were carried into effect by the Act of 1855, 18 and 19 Vict. c. 72, for legalising and preserving the restored standards of length and weight, sec. 1 of which repealed the provisions of the Act of 1824 concerning the restoration of the standards by reference to the pendulum and to the weight of a cubic inch of water.

Under the provisions of the Act of 1855, the imperial standards were deposited in 1855, in the office of the Exchequer. On the consolidation of the ancient Office of the Exchequer with the Audit Office in 1866, and the creation of the Standards Department of the Board of Trade, under the Standards Act, 1866, 29 and 30 Vict. c. 82, the custody of the imperial standards was transferred to the Warden of the Standards, the head of the new Standards Department, and the imperial standards are now deposited in a fireproof iron chest in the strong room in the basement of the Standards Office, which has been specially adapted for their safe preservation. Provision is contained in the Act for the comparison once in every ten years of the three Parliamentary copies of the imperial standards deposited at the Royal Mint, in charge of the Royal Society, and in the Royal Observatory, Greenwich, respectively, with the imperial standards of length and weight, and with each other. Under this Act new scientific duties were also imposed upon the Standards Department, the Warden of the Standards being charged with conducting all such comparisons, verifications, and other operations with reference to standards of length, weight, or capacity, in aid of scientific researches or otherwise, as may be required.

In connection with the question of the derivation of a standard unit of length from a natural constant to be found in the ascertained dimensions of the earth, it may be added that Sir John Herschel has pointed out the fact of the length of the polar axis having been determined, from the combined results of all the scientific measurements of arcs of the meridian, to be equal to 500,482,296 inches of our imperial standard yard, and that if one five-hundred-millionth part of the polar axis were adopted as a new standard unit, to be called the "geometrical inch," it would differ from the imperial inch less than one-thousandth part of an inch; a difference so small as not to be measured by any ordinary method, and only by the aid of the nicest scientific instruments. For all "ordinary practical purposes," the geometrical inch would be identical with the imperial inch; whilst for high scientific measurements for astronomical purposes, it would connect by an unbroken numerical chain the small units with which mortals are conversant in their constructions and operations with the great features of nature, and more especially with those greater units in the measurements of the universe with which astronomy brings us in relation. It would also produce a more exact ratio between our units of length and weight, the avoirdupois ounce being nearly a "geometrical ounce," or one-thousandth part of the weight of a geometrical cubic foot of distilled water. That is to say, whilst the existing legal weight of a cubic foot of distilled water is 997·136 ounces, the weight of a geometrical cubic foot of water would be 998·1 ounces. And as the imperial half-pint is the measure of ten ounces of distilled water, the ratios of these units of length, weight, and capacity would thus be brought within such practical limits of precision as would meet every possible requirement of commercial exigency.

III.—*Derived Units and Multiples and Parts of Imperial Standard Units.*

THE IMPERIAL STANDARD GALLON AND BUSHEL.

With respect to measures of capacity, the sole unit of all imperial measures of capacity, established by the Act of 1824 is the standard gallon, containing 10 lbs. avoirdupois of distilled water, weighed against brass weights in air at the temperature of 62° Fahr., the barometer being at 30 inches. From the imperial standard gallon is derived the imperial bushel of 8 gallons, the standard of capacity for dry goods commonly sold by heaped measure, or incapable of being striken. Various

units of measures of capacity had been previously established in this country at different periods. In Magna Charta, three such units are recited, "there shall be throughout our realm, one measure of wine, one measure of ale, and one measure of corn." Of these, the most ancient known was the Winchester corn bushel, of the capacity of about 2150·42 cubic inches, together with the Winchester corn gallon of 272¼ cubic inches. We have no record of any other standard measures of capacity being actually constructed, until the standard ale gallon of 282 cubic inches was added by Queen Elizabeth, and the standard wine gallon of 231 cubic inches by Queen Anne. All these old standard measures were discontinued as legal measures in 1824, and the new imperial standard gallon of 272·274 cubic inches, and the bushel of 2218·191 cubic inches, constructed and verified under Capt. Kater's superintendence, have since continued to be the standard units of imperial measure for liquids and for dry commodities.

The Exchequer standards of the imperial gallon and bushel formed part of the complete series of secondary standards constructed and accurately verified under Kater's superintendence in 1824. These standards, together with other secondary standards, subsequently legalised, have served for regulating all the commercial weights and measures of Great Britain and her colonies and dependencies from 1824 up to the present time. The Exchequer standards were transferred to the Standards Department of the Board of Trade in pursuance of the Standards Act, 1866.

H. W. CHISHOLM

(To be continued.)

THE FRENCH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE

THE session of this young Association which has just been concluded at Lyons appears to have been altogether successful, and according to the Reports read the Association is in an exceedingly prosperous condition, both as to number of members, income, and the carrying out of the scientific aims which it has in view. The number of members who attended the Lyons Congress was very satisfactory. The capital fund at the end of 1872 was 136,464 francs, and the income for 1873 is expected to be 24,000 francs. One of the aims of the Association is to give an impulse to Science in the provinces, and, as we recorded some time ago, the members of the Association resident about Bordeaux have formed a local association, and it is hoped a similar result will follow in the case of each town where the yearly meetings are held. The Association has received invitations for its next session from various French cities, and it has been decided to hold the meeting of 1874 at Lille. M. Wurtz was elected President for the ensuing year.

The accounts which have come to hand are mainly concerned with the work done in the Medical Section. Last week we gave a few extracts from the Presidential Address of M. De Quatrefages, and shortly we hope to be able to give a *résumé* of the work done in the various sections, as well as of the more important public lectures. Meantime we shall give a brief sketch of the general work which has been done.

In the general meetings, Dr. Blanc, an Indian military surgeon, read an important paper "on the means of arresting the propagation of cholera," founded on experiments made by himself. M. A. Gaudry, Professor at the Jardin des Plantes, Paris, gave a lecture on a botanical subject. Dr. Bertillon also gave a lecture on "Demography," *i.e.* the Natural History of Society. M. de Lesseps talked in a familiar and pleasant way of the proposed railway across Central America. M. F. Papillon read a paper on the connection between the Sciences and Metaphysics, and the Abbé Ducrost gave a lecture on the Prehistoric Station of Solutré.

The part of the Congress which is undoubtedly the most attractive consists in the excursions and the public lectures; the former interest strangers, and the latter, members. Besides the special excursions organised by certain sections and parties of members, there have been three general excursions—one to the prehistoric station of Solutré; a second to the sides of the plateau of Les Dombes; a third to the mines and furnaces of Voulte-sur-Rhône, in Ardèche, and a fourth, which set out last Friday and was to last for two days, to Geneva and the shores of its lake.

There have been three public lectures: the first was given by M. Karl Vogt, of Geneva, on Volcanoes; the second by M. Janssen, on the Physical Constitution of the Sun; and the third by M. Aimé Girard, on the Recent Progress of Industry.

NOTES

THE final arrangements for the Bradford meeting of the British Association are as follows:—The first General Meeting will be held on Wednesday, Sept. 17, at 8 P.M. precisely, when Dr. Carpenter, LL.D., F.R.S., &c., will resign the Chair, and the President-Elect, Prof. W. A. Williamson, F.R.S., will assume the presidency, and deliver an Address. On Thursday evening, Sept. 11, at 8 P.M., a Soiree; on Friday evening, Sept. 19. at 8.30 P.M., a discourse by Prof. W. C. Williamson, F.R.S., of Manchester, on Coal and Coal Plants; on Saturday evening, Sept. 20, a Lecture on Fuel to working men only, by Mr. Siemens, F.R.S.; on Monday evening, Sept. 22, at 8 30 P.M., a Discourse on Molecules, by Prof. Clerk Maxwell, F.R.S.; on Tuesday evening, Sept. 23, at 8 P.M., a Soiree; on Wednesday, Sept. 24, the concluding General Meeting will be held at 2.30 P.M., and in the evening a Grand Concert will be given in St. George's Hall, at 8 P.M. The excursions on Thursday, Sept. 25, will be to Harrogate, Ripon, Studley, Bolton Abbey, Gordale Scarr, Malham, Clapham Caves, Settle Caves, and Ingleboro'. Lists and prices of lodgings, and other general information will be given, on application at the Local Secretaries' Office, Bradford.

IT is said that a portion of the immense wealth of the late eccentric Duke of Brunswick is to be devoted to the founding of a Faculty of Medicine in Geneva.

THE King of Prussia has conferred on Prof. Helmholtz the Order of Merit for Science and Art.

THE October number of *Petermann's Mittheilungen* will contain an account of Professor Nordenskiöld's Arctic Expedition during 1872-3, in the direction of Spitzbergen, which has not, geographically, been very successful. The steamer *Solhem* reached Tromsö on August 6, and the following telegram of that date has been received from Prof. Nordenskiöld:—"Just arrived here, all well. My resolution to undertake another ice-journey towards the north after the sledge-journey round North-east-land, has been rendered impracticable through want of provisions, which has compelled us to return. Instead of this we have undertaken extensive deep-sea dredgings as well as botanical, magnetic, and geological researches. I bring with me, besides other from various formations, very important collections of Miocene flora, as well as of two formations which belong to an older geological period hitherto altogether unknown in the Polar regions. These collections throw new light upon the prevailing flora and the climate of former periods, as well as upon the changes which these have undergone."

ACCORDING to the report of the Meteorological Department an earthquake occurred at Nottingham at ten minutes to seven o'clock on Friday morning last.

PROF. PALMIERI stated in the Neapolitan papers on Aug. 12, that, according to observations on Vesuvius, new earthquakes may be expected.

THE Berlin medical journals record the death, from cholera, on August 20, of Dr. Otto Obermeier. His death is supposed to have been the immediate consequence of his intense devotion to Science. Having too great confidence in his power of resisting infection, in consequence of having not taken fever during his investigations on that disease, he kept in his bedroom pathological specimens taken from persons who had died of cholera, and also portions of their excreta; and it is believed that in this way he became infected. According to one account, he injected some blood from cholera patients into his own vessels. He was so devoted to his inquiry that, after he had become aware of the condition in which he was, he made some microscopic examinations on his own blood. His death occurred after an illness of seven hours, in the thirty-first year of his age.

THE late Mr. John Stuart Mill has left property to the amount of 14,000*l.* Of this he has left to any one university in Great Britain or Ireland that shall be the first to open its degrees to women, 3,000*l.*; and to the same University a further sum of 3,000*l.* to endow scholarships for female students exclusively. His copyrights he bequeaths in trust to Mr. John Morley, to be applied in aid of some periodical publication which shall be open to the expression of all opinions, and which shall have all its articles signed with the names of the writers.

THE planet No. 131, discovered by Prof. Peters, has been named Vala.

No. 1,952 of the *Astronomische Nachrichten* contains the following ephemeris of the one discovered by M. W. Tempel at Milan on July 3 last:—

1873.	R.A. h. m. s	South Declination. ° ′
Sept. 4	2 7 17	14 38
,, 8	2 9 0	15 26
,, 12	2 9 58	16 12
,, 16	2 10 15	16 54
,, 20	2 9 52	17 31
,, 24	2 8 49	18 6

This ephemeris is by Signor J. V. Schiaparelli; it is for 0 h. Milan time. The same number of the *Astronomische Nachrichten* contains a short article upon this comet by Mr. L. Schulhof, assistant at the Observatory of Vienna, wherein he says, "It does not admit of doubt that we have here to do with a periodic comet of short revolution, the exact calculation of the orbit of which I shall enter upon without delay."

TWO new comets have been recently discovered; the one by M. Henry, at Paris, the other by M. Borelly, at Marseilles.

M. STEPHAN, the Director of the Marseilles Observatory, has succeeded in re-finding Brorsen's comet. The correction of Mr. Plummer's ephemeris is as follows:—

$$\text{R.A.} + 2^h\ 7^m$$
$$\text{Dec.} - 15'\ 8''$$

WE understand that the Board of Examiners for the mining district of South Durham, Whitby, and Cleveland allow candidates for examination, under the New Mines Regulation Act, to count one or two years passed at the College of Physical Science in Newcastle the same as the like period served under indentures to a mining engineer, or as one or two years' experience in a mining office. This offers a very great advantage to young men who intend to devote themselves to the profession of mining engineering.

THE following candidates have been successful in obtaining Royal Exhibitions of 50*l.* per annum for three years and free admission to the courses of instruction under the Science and Art Department:—Royal School of Mines, Jermyn Street, London: William Hewitt, aged 21, teacher; C. S. Fleming, 20, assistant teacher; Samuel Barratt, 22, assistant teacher. Royal College of Science, Dublin: Henry Louis, 17, student; Robert H. Reilly, 18, student; Thomas Arnall, 22, rule-maker.

A SUM of 500*l.* having been placed at the disposal of the Council of the Society of Arts, through Sir William Bodkin, by a gentleman who does not wish his name to appear, for promoting, by means of prizes or otherwise, economy in the use of coal for domestic purposes, the Council have decided to offer the following prizes: Five prizes for carrying out the purpose of the donor, each prize to consist of the Society's medal and 50*l.* Testing-rooms will be provided, in which the various competing articles may be tested in sucession, each competitor having allotted to him in turn a room and chimney, for a limited period, where he may fix his apparatus for the purpose of its being tested by the judges appointed by the Society of Arts, the same to be removed when directed by the judges; such fixing and removal to be at the cost of the competitor. The competing articles must be delivered at the London International Exhibition, South Kensington, on December 1, 1873, with a view to their being tested, and subsequently shown in the Exhibition of 1874.

THE last number of the *Society of Arts' Journal* contains a Report on Cooking Apparatus at the International Exhibition, by Mr. G. W. Yapp.

IT is stated that a new Literary Review will be published at the beginning of next year, covering the same ground as the *Athenæum*, the *Academy*, and *Notes and Queries*. It will supply a regular weekly account of English and foreign literature, science, and learning, the fine arts and archæology, music, and the drama. It is added that the proprietors have purchased all rights in the *Fortnightly Academy Journal*, and intend to make that the scientific and learned part of the new paper, though whether under the name of the *Academy* or some other name is not yet determined.

A LIFE of Claparède, with an admirable portrait, precedes his posthumous work, entitled "Recherches sur la structure des Annélides Sédentaires," which is published as the new volume of the "Memoires de la Société de Physique de Genève."

WE have received a little pamphlet containing a very interesting account, by Mr. J. Logan Lobley, of the excursion of the Geologists' Association to the Malvern district during the 21st and five following days of last month.

WE have received Reports of the meetings of the Eastbourne Natural History Society for April 18 and May 23. At the former meeting, a paper by Miss A. Woodhouse was read on *Odoxa moschatellina*, and the Rev. A. K. Cherril read one "On Mosses." At the latter meeting the following papers were read:—"The Orchidaceæ, with special reference to the species found near Eastbourne," by Miss Hall and Miss A. Woodhouse; *Ceratostoma Helvellæ*, by C. J. Muller; and "The Alluvial Beds of the Wish," by the Rev. E. S. Dewick, F.G.S.

A CORRESPONDENT writes us that he has just obtained a specimen of quartz with gold found at Wanlockhead, Dumfriesshire. It is a fragment of a detached mass of quartz which weighed about ten pounds, throughout which gold was diffused. Gold has long been collected from the sand of some of the rivulets at Wanlockhead and Leadhills, but no instance was before known of gold having been found in its matrix. The specimen which our correspondent has contains about as much gold as might be equal to the third or fourth of a sovereign, along with brown iron ochre diffused over one of the surfaces of the quartz.

A DESPATCH from Havana, dated August 19, states that late advices from Lima and Peru report a serious accident had occurred sixty miles from that city. A body of earth, estimated at 10,000,000 cubic yards, fell from a mountain side into a valley, severely injuring a number of persons, and damming up a river, the water of which had risen 109 feet above its usual height. Engineers were of opinion that the water would soon burst its barriers, when it would rush towards Lima, sweeping everything before it, and submerging the lower portion of the city. Several towns in Chili had been greatly damaged by earthquakes.

As the result of a recent careful study of the drug *Pareira brava*, Mr. Daniel Hanbury has discovered that, instead of its being obtained from *Cissampelos pareira*, of the natural order *Menispermaceæ*, the genuine *Pareira brava* is the stem and root of a plant which he has identified with *Chondrodendron tomentosum* of Ruiz and Pavon. The drug of English commerce, however, is mostly of larger size than the root of *Chondrodendron* and is of doubtful origin, the structure of the wood being also that of the order *Menispermaceæ*.

UNDER the title of "On Coal at Home and Abroad," Messrs. Longman have recently published in one volume the following three articles, contributed to the *Edinburgh Review* by the Rev. J. R. Leifchild :—1. Consumption and Cost of Coal; 2. On the Coalfields of North America and Great Britain; 3. Fatal Accidents in Coal Mines. The republication of these papers at the present time is very opportune; they will be found to contain a great deal of information on the all-important "Coal question," as well as many interesting details concerning the working of coal mines and the character and condition of the miners.

ZOOLOGISTS will find in Dr. Theodore Gill's "Synoptical Tables of Characters of the Mammalia," prepared for the Smithsonian Institution of Washington, an excellent, concise, and accurate description of the characters of the families of the Mammalia, in a form more scientific and manageable than any yet published, at the same time that the merits of the most modern suggestions are fully weighed. The biography of the subject is also exhaustively treated.

THE Brighton Aquarium is an institution which all biologists undoubtedly look to as one from which much valuable information may be obtained on points connected with the habits and peculiarities of the animals which it has such advantages in retaining. The communications made public by its "Consulting Naturalist," however, are of a character very different from what we should expect from one so favourably placed. A fresh arrival is thus announced :—"One of the funniest little 'cusses' ever turned out of Nature's workshop, in the shape of a seal, made a bow to the public in the Brighton Aquarium a few days ago." This is followed, later on, by a *quasi* advertisement of the concert given in the building, in which the seal is playfully made to do duty as the butt for pun and slang quotation.

THE additions to the Zoological Society's Gardens during the past week include two Persian Sheep (*Ovis aries*), presented by Mr. W. H. Shirley; a Diamond Snake (*Morelia spilotes*) from New South Wales, presented by Mr. H. Frieland; two Robben Island Snakes (*Coronella phocarum*), presented by the Rev. G. H. Fisk; two Chubb (*Leuciscus cephalus*) and a Barbel (*Barbus vulgaris*) presented by Mr. E. S. Wilson; two Ring-tailed Lemurs (*Lemur catta*) from Madagascar; a King Parakeet (*Aprosmictus scapulatus*) from New South Wales; a Black Cuckoo (*Eudynamys orientalis*) from India, purchased; a Weeper Capuchin (*Cebus capucinus* and a White-throated Sapajou (*C. hypoleucus*) from America, deposited.

A POSSIBLE NEW METHOD OF ELECTRICAL ILLUMINATION

IT will be in the recollection of the readers of the *Journal*, that, in April last, an analogy was pointed out between sunlight and the electric light, and that certain conditions were therein indicated as being most favourable to that particular development of light which would best bring out the separation of the power producing the light from the place of its manifestation. Those conditions were the employment of magneto-electricity, and the use of a closed incandescent conductor in an atmosphere which would not oxidise or otherwise affect the durability of the light-producing material. From the quotation from the Russian paper *Golos* which follows, it will be seen that the results anticipated are even now in the course of realisation, and all that practical men can do is, to wish the plan the success it seems to deserve, and to wait the result of the further exhibitions of its power in London and other places more accessible to the Western nations than St. Petersburg :—

"On Tuesday the 8-20 of May, a most interesting trial was made for the first time in public at the Admiralty House, St. Petersburg, under the auspices of Messrs. S. A. Kosloff and Co., the proprietors of the patent, of a new system of lighting by electricity, the invention of Mr. A. Ladiguin, of that town.

"Owing to the restricted space in the hall made use of on this occasion, the number of spectators was necessarily limited, but still they consisted of more than a hundred specialists from different countries, representatives of science, honourable visitors, and many reporters, who were all deeply interested, and unanimously decided that the trial was really successful.

"Up to the present time, as is well known, the electric light has been used only for lighthouses, as an electric sun illumination for signals, or on the stage, where a strong light may be required without regard to cost; but thus far it has been quite impossible to employ it for lighting streets or houses.

"By the old method the electric spark was passed between two points of charcoal, each attached to a copper wire connected with an electro-magnetic machine.

"The disadvantages attending this mode consisted in the facts that, for each light a separate machine was required, and that the light so obtained, although very powerful, was impossible to be regulated, besides being non-continuous, owing to the rapid consumption of the charcoal points from exposure to air.

"All these difficulties Mr. A. Ladiguin has tried and apparently overcome most successfully.

"By his newly-invented method, only one piece of charcoal or other bad conductor is required, which being attached to a wire connected with an electro-magnetic machine is placed in a glass tube, from which the air is exhausted, and replaced by a gas which will not at a high temperature combine chemically with the charcoal. This tube is then hermetically sealed, and the machine being set in motion by means of a small steam-engine, the charcoal becomes gradually and equally heated, and emits a soft, steady, and continuous light, which, by a most simple contrivance, can be strengthened or weakened at the option of those employing it; its duration being dependent solely on the electric current, which of course will last as long as the machine is kept in motion.

"Taking into consideration the fact that one machine, worked by a small three-horse power engine, is capable of lighting many hundreds of lanterns, it is evident what an enormous advantage and profit could be gained by the illumination of streets, private houses, public buildings, and mines with the new electric light. In the latter it must prove invaluable, as no explosion need ever be feared from it, and these lanterns will burn equally as well under water as in a room.

"Without mentioning the many advantages this mode of illumination has over gas, which by its unpleasant odour and evaporation is slowly poisoning thousands of human beings, and from which explosions are frequent, we can state that by calculations made, this electric light can be produced at a fifth of the cost of coal gas.

"We hope shortly to place before the public more complete particulars, as well as reports of further experiments which are proposed to take place in Vienna, Paris, and London.'

* From the *Journal of the Society of Arts*.

GROWTH OR EVOLUTION OF STRUCTURE IN SEEDLING PLANTS*

THE continuous absorption of oxygen, and formation of carbonic acid, is an essential condition of evolution of structure, both in plants and in animals.

The above proposition in so far as it relates to animals will probably be admitted by all; the opposite opinion is, however, commonly held as regards plants; yet we propose to show that in these organisms, as in animals, growth as applied to evolution of structure, or organisation of material provided, is inseparably connected with oxidation.

The discussion of the proposition in question necessarily involves a preliminary view of the character of the gases exhaled from various plants. Commencing with the lower organisms as fungi, the uniform testimony is that these plants at all times expire carbonic acid, while it is chiefly in the higher plants, and especially in those which contain chlorophyll or green colouring matter, that carbonic acid is absorbed and oxygen exhaled. The inquiry then in reality narrows itself down to the examination of the growth of chlorophyll-forming plants.

Regarding these plants the statement is made and received, that they change their action according as they are examined in the light or in the dark, exhaling oxygen under the first condition, and carbonic acid under the second. Various explanations of this change of action have been given, that generally accepted accounting for it on the hypothesis of the absorption of carbonic acid by the roots, and its exhalation by the leaves when light is no longer present.

The change, on the contrary, appears to arise out of the fact that two essentially different operations have been confounded, viz: the actual growth or evolution of structures in the plant, and the decomposition of carbonic acid by the leaves under the influence of the light, to provide the gum or other materials that are to be organised. These two factors are separated by Prof. J. W. Draper in his discussion of the conditions of growth in plants. We propose to show that by adopting this proposition of two distinct operations in the higher plants, all the apparent discrepancies regarding the growth of these plants are explained.

The growth of seedlings in the dark offering conditions in which the act of growth or evolution of structure is accomplished without the collateral decomposition of carbonic acid, I arranged two series of experiments in which growth under this condition might be studied and compared with a similar growth in the light. That the experiments might continue over a sufficient period of time to furnish reliable comparative results, I selected peas as the subject of trial, since these seeds contain sufficient material to support the growth of seedlings for a couple of weeks.

To secure as far as possible uniformity of conditions between the dark and light series, and also to facilitate the separation, cleansing and weighing of the roots, each pea was planted in a glass cylinder, one inch in diameter and six inches long. These cylinders were loosely closed below by a cork, and filled to within half an inch of the top with fine earth or vegetable mould. They were then placed erect in a covered tin box or tube stand in such a manner that the lower end dipped into water contained in the box, while the whole of the cylinder except the top was kept in the dark. Thus the first condition for germination, viz., darkness, was secured; the second, warmth, was supplied by the external temperature, which varied from 70° to 80° F., while regularity and uniformity in the supply of moisture in both series was secured by having a box of cylinders or tubes for each and keeping the level of the water the same in both. The supply of oxygen was also equal and uniform, since the upper part of each tube presented a similar opening to the air.

Thus prepared, one box containing five cylinders was kept in a dark closet, while a second, similar in all respects, was placed in a window of an adjoining room, where it was exposed to direct sunlight five or six hours every day. To each tube a light wooden rod thirty inches in length was attached, and on this the growth of the seedling was marked every twelve hours. The hours selected were 7 A.M. and 7 P.M. I thus obtained the night and day, or dark and light growth of every seedling, as long as those in the dark grew. The seeds were planted on June 1st, and appeared above the ground on June 6th, when the measurements were commenced. In each series one seed failed to germinate; the record, consequently, is for four plants in each, and the history of the evolution of structures is as follows:

Evolution of Structure in the Dark.—In Table I. the seeds are designated as A, B, C, D, and each column shows the date on which leaves and lateral growths appeared. These constitute periods in the development of the plants, which are indicated by the number 1, 2, 3, 4, 5, 6. The weight of each seed is given in milligrammes.

,,	6,	17th ,,	18th ,,	18th ,,	17th ,,

A glance at the above shows the uniformity as regards time with which the structures were evolved in each plant. It also indicates for each plant an equality in the number of periods of evolution, viz., 6, notwithstanding the difference in the weights of the seeds, and suggests that the power of evolution of structure in seedlings resides in the germ alone.

The character of the evolution in the six periods shows a steady improvement or progression.

In the first, the growth consists in the formation close to the stem of two partially developed pale yellow leaves.

The second period is similar to the first, except that the leaves are a little larger.

The third presents a pair of small yellow leaves close to the main stem, from between which a lateral stem or twig about one inch long projects, and bears at its extremity a second pair of imperfectly developed yellow leaves, from between which a small tendril about a sixteenth of an inch long is given off.

The fourth resembles the third, the lateral twig being longer, and the tendril three times as long as in the third.

The fifth is like the fourth, except that the tendril bifurcates.

The sixth is similar to the fifth, except that the tendril trifurcates.

Stem, leaves, twigs, tendrils of various degrees of complexity, all are evolved by the force pre-existing in the germ without the assistance of light.

Evolution of Structure in the Light.

Table II. was obtained in the same manner as Table I, the columns representing the days on which lateral growths and leaves appeared. Though there is not the same uniformity as in Table I, the periods are identical in both as regards the visible character of the evolution Nothing appears in the second that did not pre-exist in the first, and in the case of the seeds E and G the evolution is even deficient as regards the first and the sixth periods.

While the general character of the evolution in both series is similar, certain minor differences exist. In II. the leaves and tendrils are many times larger than in I., and they, with the whole plant, are of a bright green colour, instead of the sickly pale yellow of I.; but the light has not developed any new structure; it has only perfected those which pre-existed, and converted other substances into chlorophyll which is not an organised body.

Not only did the plants in the two series present similarities in evolution of structure, but the average weight of dry plant in each was very nearly the same, for:

455 of seeds in the dark produced 184 of dry plant, while
455 ,, light ,, 215 ,, ,,

A comparison of the parts below the ground with those above (both being dried at 212° F.) shows that the proportion of root to total weight of plant was also nearly identical, being,

* From Silliman's American Journal of Science and Art.

25 of root for 100 of plant in the dark, and
23 ,, 100 ,, light.

The close similarity in the evolution of visible structure in the light and in the dark, the small difference in the total weights of the plants grown in the same time in both series, and the close approximation in the proportional weight of root to plant, all justify the conclusion, that the growth in darkness and in light closely resemble each other, and that it is proper to reason as regards the nature of the action from the first to the second.

Another interesting fact which lends support to the opinion that the process of growth in seedlings developed in the dark is very similar to that occurring in those grown in the light, is the character of the excrement thrown out by the roots. It is well known that many plants so poison the soil that the same plants cannot be made to grow therein until the poisonous excretions from the roots of the first crop have been destroyed by oxidation. In the case of peas this poisoning of the soil takes place in a very marked manner, and I have found that in the pots in which peas have been grown in the dark, the soil is so poisoned by the excrements from the roots that a second crop fails to sprout. Does it not follow, that since in the two series with which I experimented, the excrements from the roots possessed the same poisoning action, the processes in the plants from which these excrements aaose must have been similar?

There remains an important argument concerning which nothing has thus far been said. It is to be derived from the consideration of the rate of growth in the light series during various periods of the day of twenty-four hours. If the evolution of structure in a plant in daylight is the result of the action of light, that evolution should occur entirely, or almost entirely during the day. If, on the contrary, it is independent of the light, it should go on at a uniform rate as in plants in the dark.

For the elucidation of this portion of the subject, I present the following tables; the first of which shows the growth by night, 7 P.M. to 7 A.M., of the seedlings in the dark series, compared with their growth by day, 7 A.M. to 7 P.M. The measurements were taken from the sixth to the twentieth of the month, the day on which growth ceased in the dark series:—

Table III.—*Seedlings grown in the dark*

	Night growth.		Day growth.
No. 1	$12\frac{3}{4}$ inches.		14 inches.
,, 2	$13\frac{1}{4}$,,		13 ,,
,, 3	$11\frac{3}{4}$,,		$11\frac{3}{8}$,,
,, 4	$12\frac{5}{8}$,,		$11\frac{3}{8}$,,
Average,	$15\frac{5}{8}$,,	Average,	$12\frac{3}{8}$,,

The total day growth and night growth under these circumstances are nearly equal, though there is a slight excess in favour of the night, amounting, as the table shows, to $\frac{1}{4}$ of an inch in 12 inches.

In Table IV. the growth of the light series is given in the same manner, by day and by night, for the same time, viz., to June 20. The thermometric and hygrometric conditions in both series were very similar, as indicated by the dry and wet bulb thermometers suspended in the vicinity of each set of tubes:—

Table IV.—*Seedlings grown in the light*

	Night growth.		Day growth.
No. 5	$3\frac{1}{4}$ inches		4 inches.
,, 6	8 ,,		7 ,,
,, 7	$5\frac{1}{4}$,,		$4\frac{1}{2}$,,
,, 8	$9\frac{1}{2}$,,		$8\frac{1}{2}$,,
Average,	$6\frac{1}{2}$,,	Average,	6 ,,

In the average, and throughout the table, with a single exception, not only is the uniformity in the rate of growth during the day and night shown, but the slight excess of night growth found in the series kept in the dark is likewise copied. We must therefore accept the conclusion that the act of growth or evolution of structure is independent of light, and that the manner of growth during the day is similar to that at night.

It will be noticed that the total average height attained in the light is only about half that in the dark series. The explanation of this we have already seen in the fact that in the former the leaves and tendrils were much larger than in the latter, while the dry weights were nearly the same. The material of the seed in the light series was consumed in extending these surfaces, while in the dark series it was spent in lengthening the stem.

Having established the continuous character of growth in seedlings, and the similarity of rate and nature of the process by night and by day, and admitting that at night plants throw off carbonic acid, it is not improbable that this carbonic acid arises, not from mechanical absorption by the roots, and vaporisation by the leaves, but as a direct result or concomitant of the act or process of evolution of structure.

To put the matter in the clearest form, let us first understand what growth is. It appears in all cases to consist in the evolution or production of cells from those already existing. According as the circumstances under which the cells are produced vary, so does the tissue ultimately produced vary. Cells formed in woody fibre become wood. Cells formed in muscle in their turn form muscles, but the starting point of the process in every instance is the formation of new cells.

If now we examine the evolution of cells under the simplest conditions, as, for example, in the fermentation that attends the manufacture of alcohol, we find that with the evolution of the torulæ cells carbonic acid is produced. The two results are intimately connected, and it is proper to suppose that since the carbonic acid has arisen along with the new cells, the latter operation must in some way involve a process of oxidation. Accepting the hypothesis that oxidation is attendant on these processes of cell growth under the simplest conditions, we pass to the examination of what occurs in the lowest forms of vegetable organisms found in the air.

The fungi, and indeed all plants that are not green, with a few exceptions, exhale carbonic acid and never exhale oxygen. In this case, in which cell production often occurs with such marvellous rapidity, the carbonic acid must have arisen as a consequent of the cell growth. It is improbable that it has been absorbed by roots and exhaled from the structures, either in these plants or in those produced during fermentation. In the latter there never are any roots, and in the former, even where roots are present, they bear a small proportion to the whole plant. The quantity of moisture exhaled by such growths is also insignificant, and out of proportion to the carbonic acid evolved. We must, therefore, in this case decline to accept the root-absorption hypothesis, and admit that the carbonic acid has arisen as a result of the cell growth in the plant.

Passing to the chlorophyll-bearing plants, we find that in the Phanerogamia it is only the green parts that at any time exhale oxygen, and then only under the influence of sunshine. The other parts of the plant above the ground, that are not green, viz., the stem, twigs, flowers, &c., are at all times, day and night, exhaling carbonic acid. The whole history of the plant, from the time the seed is planted, to its death, is a continuous story of oxidation, except when sunlight is falling on the leaves. The seed is put into the ground, and during germination oxygen is absorbed and carbonic acid exhaled. If the seedling be kept in the dark, oxygen is never exhaled, carbonic acid is, and the plant not only grows, but all visible structures except flowers are formed in a rudimentary condition. In the light the growth during the night time is attended by the evolution of carbonic acid, while during the day time the bark of the stem and branches is throwing off carbonic acid. When flowers and seeds form, the evolution of carbonic acid attending this highest act of which the plant is capable, is often greater than that produced at any time in many animals.

Everything in the history of plants, therefore, tends to show that the evolution of their structures is inseparably attended by the formation of carbonic acid; and it seems impossible, when we consider the evolution alone, to arrive at any other opinion than that already expressed—that, all living things, whether plant or animal, absorb oxygen and evolve carbonic acid, or some other oxidised substance, as an essential condition of the evolution of their structures.

J. C. DRAPER

SCIENTIFIC SERIALS

THE first number of the *Zeitschrift für Ethnologie* for 1873, opens with an interesting paper by Dr. George Schweinfurth on the Monbutta Tribes of Central Africa, whose name and existence have hitherto been unknown to us. Dr. Ori and M. Jules Poncet had shown that there were important streams south of the Miam-Miam Territory, which took a westerly course, and that the banks of the most considerable of these rivers were

occupied by a brown-skinned race differing widely from the contiguous negro tribes, both in colour and in civilisation. These are the Monbuttas, known also to the ivory-traders as the Guruguri, in allusion to their practice of boring their ears. Their country, which Dr. Schweinfurth visited in 1868, and where he remained for five weeks under the special protection of the king, Munsa, is a densely populated district lying between 3 and 4 N. lat., and 28 and 29 E. long., and bounded on the north by the Kibali, a copious stream which unites with the Gadda, and under the name of Uelle receives in its passage through the Miam-Miam country a number of other streams, that serve as feeders to Lake Tsad. The country of the Monbuttas, lying at an elevation of from 2,500 to 3,000 ft. above the level of the sea, consists of an ever-varying alternation of gently swelling hills and well-watered valleys, alike rich in palms and bananas, and every other form of luxuriant tropical vegetation. In this earthly paradise where Nature spares man the burden of labour, the people, although living under an organised system of government, and showing extraordinary skill in working metals and in other arts, are habitual cannibals. This is not from want of animal food, as elephants, buffaloes, antelopes and wild swine abound, but whatever the cause may be, the fact is undisputed that the cannibalism of the otherwise gentle Monbuttas exceeds that of any other known African nation, and is systematically gratified at the expense of the more degraded blacks living beyond their frontiers, whom they seize and carry away, driving their captives before them like a herd of sheep, and slaughtering them as they need them. The young children and the fattest individuals are kept for the royal kitchen, where the flesh is dried and prepared with capsicums and many savoury fruits for the king, Munsa, whose numerous wives have to take it in turn to cook for him. The power of the king is supreme, and it would appear that the land of the Monbuttas may rank as one of the most important monarchical states of Central Africa. In race the people seem to approximate to the Fulbe, and in language to the north equatorial African group. They recognise one supreme being, appear to have no outward symbols of worship, and practise circumcision.—Dr. P. Langerhans has a paper in this number on the anatomical features of interest belonging to a series of facial and cranial measurements, with the corresponding photographs, taken at Jerusalem from among the mixed population of Khurds, Armenians, and Negroes (from Dâr). As a contribution to human comparative anatomy the paper will be found useful.—Those interested in the study of the prehistoric remains of Holland and the Low Countries generally will find much serviceable matter in a paper by Dr. Friedel, who points out the distinctions between the Frisic-Germanic and the Celtic-Batavian remains, and passes in review the collections preserved in the various Dutch museums, of which that of Leyden is the most valuable in an ethnological point of view.

Poggendorff's Annalen der Physik und Chemie, No. 5, 1873.—This number contains several papers on electricity. Dr. Hermann Herwig investigates the influence of free electriciiy at the surface of electrodes, on electro-dynamic phenomena. His experiments were made with a delicate electro-dynamometer, in which the deflections of the bifilar and multiplier coils were compared, the electro-motive force and resistance being varied.—A paper by M. Edlund treats of the chemical action of the galvanic current and the distribution of free electricity on the surface of an electrode. The author applies his theory (of electricity being a phenomenon of the luminiferous ether), to the decomposition of water by a current, and institutes a comparison between what occurs in a ring-tube in which a gas is forced into circulation from a certain point, with the phenomena in a galvanic circuit. In another note the same author opposes von Bezold's explanation of "disjunction currents," which he thinks are due to an electro-motive force in the voltaic arc itself, not to a difference in tension between the electrodes.—M. Wüllner describes experiments confirming his former assertion (questioned by Schuster) that nitrogen, in Geissler tubes, gives both a band and a line spectrum. A valuable series of experiments on heat consumption in the solution of salts, and the specific heats of salt solutions is detailed by Dr. Winkelmann, who here extends the previous work of Graham and Person on the subject.—There are also papers on the change of volume of solid substances through the formation of chemical combinations of the same aggregate state (W. Muller), on the pole-points of a magnet (Riecke), on the dynamical principle of Hamilton in thermo-dynamics (Szily), on a new mode of exhibiting metallic spectra (Edelmann), and one or two others.

THE July and August numbers of the *American Naturalist* contain, among others, the following papers:—Dr. Elliott Coues discusses the relationship between the Prairie Wolf, or Coyoté (*Canis latrans*), and the common dog, taking a pointer as his type, which is much of the same size. The physiognomy of the former is said to be between that of a wolf and a fox, "but more doggy than either." Its affinities with the dog are shown to be extremely close.—Mr. T. M. Trippe gives reasons for instances of irregular migrations of birds, showing that some depend on human interference, and changes in climate, and others are as yet unexplained.—Prof. Verril describes a new species of Octopus (*O. bairdii*) from the bay of Fundy. It is somewhat related to *O. groenlandicus*, but differs in the hectocolylised arm being longer and otherwise different.—Alexander Agassiz, in a fully illustrated article, gives reasons in favour of the supposition that the pedicellariæ and spines of Echinodermata are only modifications of a single type form, to suit different purposes in the animal's economy.—Prof. W. J. Beal, on the phyllotaxy of cones, shows that the well-known laws of phyllotaxis are very general, nevertheless there are exceptions to them, well marked among some cones, as is proved by the author's examination of a very large number from the Norway spruce, in which $\frac{3}{8}$ and $\frac{5}{13}$ were the common fractions.—Mr. A. S. Packard, jun, treats of the distribution of Californian moths, bringing information on their peculiarities to bear on Prof. Gray's work on the distribution of Californian plants.—Dr. Theodore Gill has a paper on the status of Aristotle in systematic zoology, in which he gives very cogent reasons against that great philosopher having the knowledge of the principles of zoology which is ascribed to him by some. He concludes that "there is not the slightest evidence of any recognition of what is now understood by classification in any of the extant treatises of Aristotle on animals, and the systems framed to embody his generalisations have been constructed from isolated sentences wrested from their context, and simply reflect the framer's notions or his ideas as to what Aristotle might have supposed."—Prof. Bessey notes the sensitiveness of the stamens of *Portulaca* and *Claytonia*.

Mittheilungen der Naturforschenden Gessellschaft in Berne, 1872.—Prof. Dor has an article, in this number, on colour blindness. Various experiments are described; the method most preferred having been that of viewing spectral colours with a polarisation prism. The author rejects the Young-Helmholtz theory, which, as is known, supposes three colour-perceiving elements in the retina, those for perception of red, those for green, and those for violet (or blue). Among his objections are these: absence of anatomical proof; distinct vision of many of the colour blind; the spectrum as observed by two persons, brothers, who had no perception of red or violet, was of normal length; all the pathologically colour blind suffered from atrophy of the optic nerve through cerebral or spinal injuries; in these cases, the fibrous and cellular layer of the retina, and the optic nerve, to the brain, were atrophied, but not the rods and cones; in retinal disease, on the other hand, the perception of colours is not perverted, though diminished. He concludes that colour blindness is a cerebral affection.—A note by Dr. Adolph Vogt treats of the drainage of towns, in view of a faulty state of things at Berne.—The action of Buss's new governor is discussed in a paper of some length by the inventor.—Dr. A. Forster communicates a note on the falling stars of November last, also meteorological observations at the Berne Observatory during 1872. From the curve of daily temperature variations at Berne it appears that these are sometimes considerable, *e.g.* 18·6° C. in 24 hours, a fact of significance for health.—We may further note, in this number, some contributions to local botany, by Dr. Wydler.

SOCIETIES AND ACADEMIES

BELGIUM

Royal Academy of Sciences, June 7.—M. Quetelet presented a note on the solar eclipse of May 26, 1873.—M. Montigny gave the results of a second series of experiments made on the spire of Antwerp Cathedral, in which he determined barometrically the heights at several points, in winds of different direction and velocity. His tables show a difference between the calculated height and the real height, the latter being greater for winds of the eastern semicircle, while the former is greater

for westerly winds. In north and south winds, and those closely neighbouring, the heights measured both ways closely agreed. The differences between true and barometric altitude for the same gallery increase regularly, but in contrary directions, from the meridian to the azimuths east and west, when they each attain their maximum value. The height, barometrically measured, increased, as a rule, with the velocity of the wind. No connection was demonstrable between barometric height and inclination of wind. Observations at Namur and Brussels are compared with those at Antwerp, and show a cycle like that just described, only the regions to which the maximum and minimum (barometric) altitude correspond are, at these places, in the contrary direction to those at Antwerp.—M. Melsens communicated a paper on the effect of reducing alcoholic drinks to very low temperatures. A liquor like brandy may be cooled to—60° C. without being painfully cold to a person taking it. From the phenomenon of congelation in ordinary and sparkling wines, M. Melsens seeks to show how wines and beer also may be improved by application of cold.—M. Louis Henry described researches on the etherised derivatives of alcohols and of polyatomic acids; also on propargylic compounds.—M. de Selys Longchamps made a third addition to his "Synopsis of the Gomphines," of which he can now enumerate 188 species (seventeen of these being new), arranged in forty-three genera and subgenera.—M. Van Beneden gave a summary account of results from a voyage to Brazil and La Plata. His main object had been to study the fauna of the American coast, and specially of Rio. He describes the frequent formation of lagoons by the deposit of a transverse bar separating the water of a bay from that of the sea. Fresh water continually entering such lagoons, their saltness disappears, and an interesting question was, how had the original ocean fauna, here enclosed, been affected by the change of physical conditions. M. Van Beneden made various dredgings in the bay of Rio (in which the tidal change of sea-level is very small), and in these lagoons, and promises future communications on the subject. He mentions having found in some lower forms of Crustacea (*Lernanthropides* and *Clavellinæ*) a double circulatory system like that in Annelides. Besides the lacunar system, in which circulates a colourless liquid having white globules, there is a complicated system of vessels with proper walls, containing red blood without globules. There is no connection; the two liquids do not mix. The colouring matter is hæmoglobin. The branchiæ and trunk, alternately contracting and dilating, put the liquids in circulation. The author also mentions having dissected a lamantin (disinterred for his benefit), and a dolphin, and describes exceptional features in both. The paper gives several interesting zoological facts.

July 5.—M. Quetelet read a paper on the calculation of probabilities, applied to the science of man; reviewing recent progress of statistical science in this direction, and giving numerical results in the case of stature and mortality.—M. Van Beneden presented two coloured drawings of Cetacea captured at the Cape of Good Hope. He thinks zoologists have too little regarded the system of coloration in such animals, and his remarks bear chiefly on this.—M. L. Henry communicated a paper on diallylic compounds, being part of a series of researches on glyceric derivatives.—M. Swarts followed with a note on some properties of pyrocitric acids.—M. Spring communicated some facts with reference to the oxygenated compounds of sulphur.

PARIS

Academy of Sciences, Aug. 18.—M. Bertrand, president, in the chair.—The following papers were read:—Fourth note on guano, by M. Chevreul. The author has found that the crystallisable matter C, described in his late notes, is an ammonia salt, and that the other body insoluble in cold water is a very complex mixture containing acid. He gave no further details.—Direct demonstration of the fundamental principles of thermodynamics, by M. A. Ledieu.—On the movements of the *Phylloxera* from place to place, by MM. J. E. Planchon and J. Lichtenstein.—M. de Lesseps demanded the appointment of a Commission by the Academy to examine his project of a Central-Asian railway.—M. Daubrée communicated a letter from Mr. Nordenskiöld, giving an account of the discovery, in recently fallen snow, of a carbonaceous snow containing metallic iron. This was first found at Stockholm; but the author, fearing that the powder might be due to the soot of the city, wrote to his brother, then in the centre of Finland, to collect snow there. The results were the same, and Mr. Nordenskiöld has obtained sufficient for a quantitative analysis which he proposed to make during the coming winter.—Researches on secondary ascending currents, and their application (continuation), by M. G. Planté.—A description of the cryptograph, by M. Pélegrin.—On algebraic left-handed curves, by M. Picquet.—Experimental researches on explosives, by MM. Roux and Sarrau.—A new method of estimating ammonia, organic nitrogen, and nitric acid in waters, soils, and manures, by M. Piuggari. The author proposed to convert all nitrogenous bodies into ammonia and nitric and nitrous acids by acting on them with a mixture of argentic chloride and potassic hydrate, and then converting the oxidised nitrogen into ammonia by nascent hydrogen. He proposed to estimate the resulting ammonia by Nessler's process, except when below 0·00001 grm., when he proposes a special re-agent, composed of two drops of phenol and 5 or 6 c.c. of hypochlorite of soda, which gives a fine blue-violet colouration to ammoniacal liquors.—On the hydrochlorate of terpene, and on the isomerism of the bodies having the formula $C_{10} H_{16} HCl$, by M. Riban.—On the variations of hæmoglobin in the zoological series, by M. Quinquaud.—On the variations of the urine under the influence of caffeine, coffee and tea, by M. Rabuteau.—On the zoological position, &c., of the parasitic Acariaus known as *Hypopus*, by M. Mégnin.—On a deposit of silicified vegetables in the coal basin of the Loire, by M. Grand'Eury.—On the existence in the quaternary period of a large glacier in the mountains of Aubrac (Lozère) by M. G. Fabre.—Note on the meteors of November 27, 1872, by M. Ch. Dufour.—On the meteors of August 9 and 10, by M. F. Tisserand.—A note on the same subject, by M. Chapelas, concluded the business of the session.

August 25.—M. Bertrand in the chair.—The following papers were read:—On Zöllner's theory of solar scoriæ as being the cause of spots, by M. Faye. The author observed that this theory as recently developed in a communication to the Royal Saxon Academy agrees better with the known facts of the motions of the spots than does Secchi's eruption theory.—On the polar planimeter, by M. H. Resal.—On the thoracic and abdominal phosphorescent organs of the cocuyo of Cuba, by MM. Ch. Robin and A. Lubvulbène. The systematic name of this insect is *Pyrophorous noctilucus* (*Elater noctilucus* L.) Direct demonstration of the fundamental principles of thermodynamics, part vii., by M. A. Ledieu.—On the rapidity and reproduction in the *Phylloxera*, by M. Lichtenstein.—On a principle of union in universal chemistry, as applicable to organic chemistry, by M. E. Martin.—A letter was received from M. Wolf announcing the discovery of two new comets by MM. Boreilly and Paul Henry.—On the spectrum of comet III., 1873, by MM. Wolf and Rayet.—On the spectrum of the solar atmosphere, by M. G. Rayet. The author announces the discovery of the fact that the least refrangible of the two D lines is longer than the other, as he saw the former reversed when the latter was invisible.—Twelfth note on the effects of barometric changes on life, by M. P. Bert.—On hay-fever, by M. E. Decaisne. The author asserted that this disorder has no actual existence as a separate disease.—Experiments on the scolex of *Tænia mediocanellata*, by M. Saint-Cyr.—On the movements of the stamens in *Ruta*, by M. G. Carlet.

THURSDAY, SEPTEMBER 11, 1873

THE ENDOWMENT OF RESEARCH

VI.

AMONG the difficulties which are likely to impede the ready realisation of the object to which attention has been drawn, there remains one which will always be most keenly felt by those who have devoted the most thought to the question. Beneath the word "Science" there lurks a distressing ambiguity, which, though it may not force itself upon the attention of the devoted students of any particular branch, is always arising when the general claims of scientific study come on for discussion. For our present purpose it is particularly important to attach that meaning to the word which, while best justified by usage, is also most calculated to conciliate good will from all quarters.

It will hardly be denied that the name primarily belongs to those sciences called by way of distinction "natural," in the name of which this journal is conducted, and which therefore it is needless to enumerate here; and that the name is thence transferred, by reason of analogies of varying degrees of strength, to those other branches of knowledge which either in their logical methods or positive results approximate to the standard of the physical sciences. Although it would be presumptuous to attempt to lay down with exactness the line which must somewhere exist between scientific and unscientific knowledge, it must yet be always necessary to treat with much suspicion the claims of mere erudition and of social theorising to be admitted to the honoured name. The old-fashioned reputation of the grammarian or the divine, and the modern popularity of practical reformers, are neither of them grounds on which to found a title to national endowment. The unprofitable studies for which the Universities were once famous have for centuries been abundantly rewarded, and the applause of a crowded congress is ever ready to acknowledge the merits of a novel speculation in Sociology. It is not unnatural that those who know by hard experience what Science really is should jealously uphold the dignity of their pursuits, and point with pride to the innumerable advantages which mankind within the last century has reaped from their labours: but, on the other hand, the warning is not unneeded at the present day that the field of the physical sciences is not equal in extent to that which all scientific knowledge can comprehend, and that the appeal to utility may be turned into a fallacious argument. Yet further, it may be urged that those among the sciences which most attract the public attention at the hands of an accomplished experimentalist, and of which the direct practical applications are manifest to all, are least in immediate want of support from national endowments. It is for the languishing departments of Science, which have not been popularised, and of which the results have not yet been turned to commercial value, that the advantages of endowment are most required. As soon as ever the main principle of these articles is publicly recognised, the more advanced and most useful are certain to obtain sufficient care, but it is for the more backward and the least profitable that the need of help is most urgent.

It may be reasonably expected that the Universities, as their traditions become modified under the influence of the public demands, will be disposed to accept the duty of endowing scientific research under the limitations above indicated. They can have no antecedent prejudice in favour of those branches of science which either attract the most spectators, or the greatest number of self-interested students. They have always refrained with anxiety both from bidding for popularity, and from preparing their pupils for the technical business of life. Their historic position also, and the peculiar responsibilities which they cannot but feel, will cause them to interpret Science in a liberal fashion. For these reasons it is confidently hoped that, while they cannot afford to disregard the paramount importance of the physical sciences, they will maintain the position to which other sciences more closely connected with their present curriculum have of late years grown. The former, on account of their rigorous methods, the positive character of their results, and the abundance of their possible applications must always hold the first place, and present a standard for the rest; but these others also, in so far as they are really matters of scientific treatment, are in their proper subordination equally fields for original research and proper objects for endowments. The example of the German Universities has familiarised our own seats of learning with the notion that the study of languages, of antiquities, and of history, are all capable of being pursued in the genuine scientific spirit, and may lead directly to the most important positive results. Abundant evidence has been given within the last few years to show that the primitive condition of mankind and the origin of civilisation are matters which may be revealed by Science. The metaphysical explanations of the last century have given way before the well-ordered facts and regular uniformities which modern inquirers have been able to discover and arrange. The products of the human mind, and the course of human action, when displayed in their simplest and most universal forms, have been proved to be proper subject-matter for Science, no less than the law of man's physical organism or the processes of external nature. The most advanced thinkers have no hesitation in saying that the origin of natural religion is capable of being disclosed by the same methods and with equal certainty as the origin of species, and that philology yields an instrument which can unfold the secrets of an unknown past as surely as the spectroscope reveals the composition of unknown worlds. Just as modern psychology has found it necessary to borrow a large portion of its materials from the kindred science of comparative physiology, so have the nascent sciences alluded to above been under a continual obligation to the methods of physical science, and especially those to which they are linked by means of the recognised science of ethnology.

By thus widely extending the meaning of the word Science, the intention has been to widen the area over which the endowments of original research may be extended, and to give an indication of the number of directions in which scientific investigation should be encouraged. As an indirect consequence it may be suggested that this aspect of the matter shows an easy method by which the don of the last generation, an acute critic merely in longs and shorts, and erudite only in Greek particles, may be

changed, without any violent transformation, into the modern scientific student. It is not so much that the subject-matter of his studies will be different, for in this respect the reform must be gradual, and is already being carried out, but that the whole spirit of his pursuit must be altered along with the tenure of his office. The principle throughout advocated is not that money should be abstracted from the Universities for general scientific objects, but that the large funds which they cannot need for the purposes of teaching, should, for the future, be devoted, not as prizes to their successful examinees, but for the support of those engaged in original scientific work: and it is contended that this is the sole means by which they can justify their retention at all of this surplus, and by which also the main objects of the first givers can be carried out. It must also be noticed that this development of our scheme brings out into greater clearness the old position that the obligation of teaching would be merely an incumbrance on our new scientific fellow. Discoveries in Science, especially those of the most important kind, are made in such a tentative fashion, and are proved by such elaborate inferences, as to be quite incapable of being communicated orally to a class; nor indeed would it be desirable that researches, as soon as made, should be forthwith promulgated from the professor's chair. The growth of Science, whether physical or not, must in many cases be militant, and may be left much more profitably to the student, who is ever investigating with a single eye to the truth, than to the teacher, who must be always careful of the form in which his doctrine is to be conveyed.

We trust, therefore, that by this attempt to show that the meaning of scientific research is not so restricted as it has been some times represented; not only has the general thesis of these articles been strengthened, but also that new adherents may be conciliated in favour of a cause which promises to connect together the followers of physical science and those at the Universities who alone worthily maintain the dignity of their ancient studies; and it must always be understood that we have looked upon the Universities as representing local State action, and that the nation must do universally what we think should be done by the University authorities locally at Oxford and Cambridge. C.

EUROPEAN SPIDERS

Remarks on Synonyms of European Spiders. By T. Thorell, Ph.D., Junior Professor of Zoology in the University of Upsala. (Upsala, 1870-73, pp. 1-644.)

FEW branches, perhaps, of entomological science show the effects of independent and isolated labours more strikingly than Arachnology—limiting this term here to the order Araneidea (or Araneæ). The great works of N. Westring on Swedish Spiders, published in 1861, that of Mr. Blackwall on those of Great Britain and Ireland, published 1861-64, and the "Catalogue Synonymique des Araneides d'Europe," by M. Eugène Simon (included in his general work "Histoire Naturelle des Araignées," published 1864), are an instance representing very strongly the fruits of this isolated labour in the same branch of natural history science. These authors appear to have been, and indeed, it is believed, actually were—the two former at all events—totally ignorant of each other's existence. M. Simon, indeed, quotes Mr. Blackwall occasionally in his "Catalogue Synonymique," but his knowledge of that author's works was apparently confined to the scanty and often erroneous quotations in Baron Walckenäers' "Insectes Aptéres." Mr. Blackwall then and M. Westring, each in his own way and with the works of other authors more or less at their common command, plodded on for years in parallel paths. Both worked diligently and laboriously, at, for a very great part, as a glance at the map would suggest, identical objects; their labours at length resulting in the respective volumes above mentioned. So much as this however can hardly be said in regard to the third one of the works noted. The "Catalogue Synonymique" bears few marks of labour at the objects themselves which it enumerates, and is in fact a mere desk work, remarkable chiefly for the limited and often infelicitous use of the materials undoubtedly available at that epoch to any author professing to gather together and to harmonise the independent and scattered morsels of an extensive branch of natural science. The good work, however, done since, and being now daily done in Arachnology by M. Simon, will soon obliterate the remembrance of the comparative failure of the more ambitious efforts of his early years.

Towards these isolated works of Mr. Blackwall and Mr. Westring the minds of Arachnologists in more than one quarter appear soon to have been directed, with a view to bring their parallel lines together. Dr. T. Thorell —of the University of Upsala—a countryman and personal friend of Mr. Westring, and an accomplished scholar, was the first to move publicly in it: and bringing great ability and clearness of head to bear upon the subject, designed an almost exhaustive work on "European Spiders." Of this work, and under that title, was published in 1869-70, Part I. with the special title of "Review of the European Genera of Spiders, preceded by some Observations on Zoological Nomenclature." This portion of the proposed work appeared in the "Nova Acta Regiæ Societatis Scientiarum Upsaliensis," ser. iii. vol. vii. Fasc. i. et ii.; but owing to some unforeseen difficulty, and unfortunately for the external continuity of the two portions of the work, the second part, intended to treat upon the more special division of the subject, was published in 1870-73 as a separate work in a different form and with an independent title, being that given at the head of this notice, viz. "Remarks on Synonyms of European Spiders;" this is, however, as may be at once seen from the respective introductions to the two, although the title of the second does not allude to it, really Part II. of the originally designed work, "On European Spiders." It is thus evident that though the present notice is upon the second work, it could not be adequately considered without first remarking briefly upon the one which preceded.

Dr. Thorell's stated object ("European Spiders," p. 1) being to fix the nomenclature of the spiders described in the works of Blackwall and Westring, it was obviously necessary first to decide upon the genera recognised by them, and by those authors also to whom they refer; and for both this and the subsequent determination of the specific name to which each spider was entitled, it was,

above all, important to lay down the rules by which the author proposed to be guided in his decision between perplexed and conflicting synonyms. It is no part of the object of this notice to criticise the rules thus laid down in Part I. pp. 3—18 of Dr. Thorell's work; suffice it to say that they are substantially those laid down by a committee of the British Association, Ann. N. H. 1, vol. xi. p. 239 *et seq.* Their general reasonableness is obvious, though in many cases their rigorous enforcement would savour of pedantry and lead to undesirable results. Another feature in Part I. of "European Spiders," that is the list of works upon Arachnology, with the name of the author and date of publication, is a useful and important one, and cannot fail materially to assist the general student as well as anyone desiring to test the justice of the author's decisions. This list is considerably enlarged in the portion of the work now under consideration, pp. 584—589.

Coming then thus to Dr. Thorell's "Remarks on Synonyms of European Spiders," we soon observe that whatever the difficulties may have been which beset the determination of the generic synonyms in Part I., these difficulties must have been immensely increased when the specific nomenclature came to be decided. The task was not merely to ascertain and fix the names of those species common to Blackwall and Westring, but those of all the authors quoted by them as synonymous, with their species, together with the names of many other species into the bargain, such as those which have been subsequently described by E. Ohlert ("Die Araneiden oder Echten Spinnen der Provinz Preussen," 1867), A. Menge "(Preussiche Spinnen," 1866—1872, not yet complete), and other authors. This laborious task Dr. Thorel has executed with exceeding care and minuteness of investigation; his plan has been first to take, by way of text, the species described by Mr. Westring, as being, with only four exceptions out of 308, known to himself from examination of the type specimens; then to determine by strict and careful comparison of figures and descriptions what species described by other authors appeared to be more or less certainly identical with those of Westring; and then which of these had priority in regard to time of publication, the date of publication being in each case placed in immediate conjunction with the names of the spider and author, and the usual reference to the name of the publication or where published. Some idea of the labour of comparison and discrimination of descriptions and figures may be obtained by the fact of the number of synonyms given of a single species, being in some instances as many as twenty-two. Each of these would form the subject of a separate investigation, independently of those, often numerous, synonyms quoted by each author cited, and which would frequently have to be investigated in a similar manner; and after all, when the frequent meagreness of descriptions and badness of figures are considered, it will be evident that the determination of synonyms must, without types of the species described for examination, be often little more than approximate guess-work; in fact it is not too much to say that the greatest care and pains bestowed upon figures and descriptions alone would give but very unsatisfactory results.

In the present instance Dr. Thorell has had the advantage (fully acknowledged in his work) of being able to examine and compare, not only the types (as before observed) of all but four of Westring's species, but also, with them, a very large proportion (nearly 250 out of 304) of those described by Mr. Blackwall, and many more described by other authors quoted in the "Synonyms." With these undeniable advantages the various considerations entering into each question of synonymic identity or distinction are detailed in a manner at once full and yet terse; and wherever a doubt has finally rested it is never slurred over or disguised.

It would be in vain to select special examples in proof of this; the details which follow the list of synonyms appended to each species, are, in almost every instance, of this thorough and honest character.

The first section of the work being occupied with the spiders described by Westring, forms by far the largest portion of the whole—pp. 1—407; for the complete determination of all the synonyms involved in this section of necessity cleared off a very large number of the species described by Mr. Blackwall. The consideration of the remainder of these forms section ii., and occupies pp. 414—470. This part ends with an exceedingly useful "List of the Spiders described and figured in Mr. Blackwall's 'History of the Spiders of Great Britain and Ireland,' together with a statement of the names believed to belong to each of them, the year in which the assumed specific name was published, and the work in which this publication took place; or instead of these last-mentioned particulars, a reference to the place in the present work where the species may have been more fully treated of." In this list, those species, about 67 in number, of which Dr. Thorell has not himself seen types, are marked with an asterisk. Section iii. contains "Synonymic remarks on some of the Spiders included in Simon's Catalogue Synonymique des Aranéides d'Europe." For reasons given in the introduction to this section, Dr. Thorell's remarks are confined to a small number of the species contained in Mr. Simon's Catalogue; in fact this catalogue, being a mere list of names, is used only as indicating some European species of general interest not contained in either Mr. Blackwall's or Westring's works.

In a work of the nature of that now under consideration, and occupying nearly three years in its appearance, it was inevitable that some errors should get in, as well as that modifications and additions should be necessitated in consequence of extended research and more accurate information obtained during that time; these, under the head of "Additions and Corrections," occupy pp. 544—582; and the remainder of the volume, pp. 582—607, is taken up with additions and corrections to that portion of the original design (mentioned at first), entitled, "On European Spiders, Part I." This is a very important, as well as interesting, *finale* to the whole, containing, as it does some further observations on nomenclature, with a disquisition on the present state of the question as to the exact functional use of the palpal organs of the male spider. Some remarks are also made upon the *fourth pair of spinners*, or inframammillary organ, discovered by Mr. Blackwall many years ago, and ascertained to be correlated (in the female spider only) with a peculiar comb-like row of bristles—calamistrum—on the metatarsi of the fourth pair

of legs. Dr. Thorell appears somewhat to doubt Mr. Blackwall's position, that this organ is in all cases a true spinning apparatus; the better opinion would appear to be that it is so.

The work ends with some very valuable remarks on the general classification of the Araneidea, or (as Dr. Thorell, with good reason, prefers to call the order of spiders) Araneæ, pp. 597—607. Within this compass some recent works and suggestions on the systematic classification of spiders by Dr. Ludwig Koch, Rev. O. P. Cambridge, Anton Ausserer, and others are reviewed and criticised; the conclusion come to being that the new and highly remarkable forms brought to our knowledge by the researches of later years shows more than ever "that a fully satisfactory classification of the order of spiders is a thing not soon to be expected, and that a by no means inconsiderable number of forms cannot without great uncertainty, even if at all, be included under the hitherto received families and higher groups." Undoubtedly, towards this satisfactory classification, by whomsoever it may be finally effected, Dr. Thorell has done good work in the volume on "European Spiders," and that on their "Synonyms." The systematiser hardly exists yet who could say with truth that he had risen from a perusal of these volumes without considerable alteration, or, at least, modification, of his own previous views on the subject.

With so much to commend, in the work under review, it may perhaps appear invidious to notice what seem, to be a defect, at least in point of form. In ths course of the minute and extensive investigation of specimens, descriptions, and figures necessary to arrive at a satisfactory determination of obscure synonyma, species here and there appeared to be new to Science, and others to require separation (under other names, and with a fresh description) from those with which they had before been confounded; these new and separate species Dr. Thorell has described in extended notes, *in loco*, in a smaller type, thus marring the continuity, and breaking in upon the expressed design of the work. Would not these descriptions have come in better, and have been more useful for study and reference, had they formed an appendix to the work?

Another defect (though its rectification might perhaps be said to have been a departure from the strict design of the work) appears to be that Dr. Thorell does not include in his volume *all* the spiders at present known to be indigenous to Europe; it details those described by Westring and Blackwall, with some others given in M. Simon's catalogue, as well as, incidentally, many more described by other authors; but still it leaves unnoticed other described species. It would have given the work a great additional value had there been a general list of all the (at that present time recorded) spiders of Europe in systematic order, or, at least, a supplementary one of all those species mentioned or detailed throughout the work, in addition to those of Blackwall and Westring. This is, however, as before hinted, rather a criticism upon the design than the execution of the work, though it seems to be invited by the author's having so far departed from his own original design as to include descriptions of new species, as well as notices of others besides those included in "Araneæ Suecicæ," "Spiders of Great Britain and Ireland," and the "Catalogue Synonymique."

It would be scarcely proper to conclude this notice of a scientific work written by a native of Sweden, without a remark upon its being written in English, and a well-deserved compliment upon the exceeding clearness and terseness of the style, and its generally happy accuracy of expression.

Dr. Thorell's own opinion—expressed in a note to page 583—and in which most English-writing naturalists will probably acquiesce—is that English will one day become the common scientific language of the world, not only because it "is far more widely diffused over every part of the earth than any other culture-language, and that already two of the greatest nations publish in it the results of their scientific labours, but because English, on account of its simple grammar, and as combining in nearly the same degree Teutonic and Romanic elements, is by most Europeans more easily acquired than any other language." The opinion, however (given in the same note *l. c.*), in regard to works written in little-understood languages, such as Russian, Polish, Bohemian, Finnish, or Magyar, will hardly be endorsed. Dr. Thorell would exclude works written in these or such like languages,[1] from equal scientific weight with others written in French, English, German &c., *i.e.*, he would not apply to the former the rules, as to priority, applied to these latter. Now, however grateful it would be to Western naturalists to have all works on Natural Science published in languages with which they are ordinarily more or less familiar, yet it would be rather too hard upon other nations, to whom the love of natural history has come sooner than a general philological culture, to be excluded from equal scientific rights with their more advanced brethren in the West. It would seem quite as just, if not more so, that if a penalty is to be paid for ignorance of foreign tongues, it should fall rather upon those who, with whatever trouble and inconvenience, certainly might become acquainted with works on Science in any language, than upon those who, preferring to write in that tongue in which they can undoubtedly think most clearly and best express their thoughts, give the results of their scientific labours in the vernacular. By all means let us have, if possible, a common scientific language, but meantime, if it be so, we must put up with the occasional annoyance of finding that a genus or species which we had fondly imagined we were the first to describe, had already, perhaps long, been well described, and possibly figured, in some unheard-of work written in an outlandish tongue not understood of the Western Scientific World.

OUR BOOK SHELF

A History of the Birds of Europe. Parts 18, 19, 20. By H. E. Dresser, F.Z.S., &c. (Published by the Author at 11, Hanover Square.)

THIS fine work continues to appear with commendable regularity every month, and keeps up its high character both for fulness of information and beauty of illustration. In the numbers now noticed are several highly artistic plates, such as those which represent the White-shouldered and Imperial Eagles, the Great Black-headed Gull, the Common Crane, the White Stork, and the Great Bustard, which each form a perfect picture. We find full but not too lengthy articles on all these, as well as on the Black Grouse, the Curlew, and many smaller birds. An excellent plan is adopted, in the more characteristic and difficult European genera, of giving a list of all the

known species, with notes of their distinguishing characters and geographical distribution. One of the most rare and interesting species figured (in Part 20) is the Teydean Chaffinch, a bird of a blue colour, and which is confined to the upper limits of the pine forests of the Peak of Teneriffe, and to the desolate plains above them, feeding on the seeds of the Retanca (a broom-like plant) and the *Adenocarpus frankenoides*, which characterise those regions, as well as on the seeds of *Pinus canariensis*.

A. R. W.

Lehrbuch der Physik, von Dr. Paul Reis (Dritte Lieferung). Leipzig: 1873.

THIS forms the concluding part of Dr. Reis's useful handbook of Physics. The subject of physiological optics is continued, followed by a description of optical instruments and the laws of the interference and polarisation of light. Heat is treated in the next part, but hardly so fully nor so well as light; radiant heat, for example, occupying less prominence than it deserves. Considerable space is devoted to the explanation of machines for the conversion of heat into motive power: thus we have some of the various forms of steam-engine described, together with a full account of Ericson's heat-engine and Lenoir's gas-engine. Magnetism follows heat, and then we come to static and dynamic electricity and the practical application of electricity. The book closes with a few chapters devoted to the physics of the heavens, or in other words a brief sketch of popular astronomy and meteorology. The principal defect of this handbook is the want of sufficient woodcuts to illustrate the apparatus referred to. The whole work exhibits the characteristic solidity and thoroughness of the German race, and is a marked contrast to some of the recent French popular text-books on Science, the profuse and beautiful illustrations in which almost supplant the letterpress. Let us flatter ourselves that in our nation these complementary races intermingle.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

Tyndall and Forbes

IT will probably be considered necessary that Dr. Tyndall's pamphlet,* which first appeared as an article in the *Contemporary Review*, be answered at full length. That, however, cannot be decided for some time, as several of those concerned are abroad; but it may be well to let Dr. Tyndall know at once that there is no difficulty whatever in answering him, and that the answer will not lose force or point by a little delay. In the meantime I hope you will give me space to briefly notice a few of the more obvious inconsistencies of Dr. Tyndall's article.

1. Dr. Tyndall is astonished that the "blameless advent" of his "innocent" "modest" "unpretending" volume should be looked upon as reiterating charges made against Forbes. An extract or two will settle this point.

a. "Had he (Rendu) added to his other endowments the practical skill of a land-surveyor, he would now be regarded as the prince of glacialists."

"Professor Forbes, when he began his investigations, was acquainted with the labours of Rendu. In his earliest works upon the Alps he refers to those labours in terms of flattering recognition. But though as a matter of fact Rendu's ideas were there to prompt him, it would be too much to say that he needed their inspiration."

Put these two passages into straightforward English, instead of Dr. Tyndall's favourite style of insinuation, and they amount to this: that Forbes, having the accomplishments of a land-surveyor, and being acquainted with Rendu's work, put this and that together and appropriated the discovery.

b. Forbes had, in 1860, minutely informed Dr. Tyndall of the nature and amount of his knowledge of Rendu in 1842. It is not too much to say that Dr. Tyndall's sentence quoted above is utterly inconsistent with the plain statement of Forbes, and so implies a serious personal charge against the latter.

c. A similar serious charge is made, when Dr. Tyndall, knowing that Forbes asserted that it was at his suggestion that Agassiz employed a theodolite or a fixed telescope, and that this had never been denied, carefully states that "the same instrument was employed the same year by the late Principal Forbes upon the Mer de Glace," and that "we are now on the point of seeing such instruments introduced almost simultaneously by M. Agassiz on the glacier of the Unteraar, and by Prof. Forbes on the Mer de Glace."

2. Dr. Tyndall tells us that his work was originally commenced as a boy's book, but that "the incidents of the past year" (*i.e.* his controversy with Forbes) caused him to deviate from this intention. Have boys so altered since 1859 that such controversy has now become suitable for them when supplied in the "International Series"?

3. What I said with reference to the unpublished correspondence of Forbes was said without any special reference to Dr. Tyndall. It was simply my excuse to the reader for the very meagre use I had made of so extensive and valuable a collection.

But, even in this matter Dr. Tyndall's inconsistency is patent. He says that, longing for peace, he abstained from answering Forbes, not from inability to do so, but to avoid making Science the arena of personal controversy. Yet, in the same breath, he not only complains of my not publishing certain letters which he supposes to contain charges against himself, but (see § 5 below) insinuates that I am acting from feelings of animosity!!

4. Dr. Tyndall's answer to one of Forbes' charges is certainly to some extent plausible. I can say no more till I have an opportunity of consulting Rendu, for it is quite obvious that it is possible by proper selection of portions of so vaguely-written a book to make him appear to say anything one chooses.

Dr. Tyndall's answer to the other charge is so obviously insufficient that I need not deal with it here.

But more than this:—no ever-so-complete defence of himself on one or two points is any reply to the overwhelming pamphlet of Forbes, every line of which in its calm truthfulness calls for an answer.

5. Dr. Tyndall refers to former controversy between us, and to its happy termination at a personal interview. Why Dr. Tyndall should bring before the public such matters as a private reconciliation, unless with the object of holding me up to scorn as the breaker of a solemn truce, I altogether fail to see. I need scarcely say that no one in his senses would enter into an agreement never in future to differ from another, nor to point out in his writings passages calculated to mislead. But the following, and other passages which I need not cite, are all so many half-mysterious insinuations (of the Tyndall kind) against me, and all tend towards the same implied accusations.

". . . the fire was not extinct: the anger of former combats, which I thought spent, was still potential, and my little book was but the finger which pulled the trigger of an already loaded gun."

I shall be obliged by Dr. Tyndall's pointing out to me a single expression, in that part of Forbes' Life which was written by me, which is calculated to give him the slightest offence:—with the one exception of a letter from Forbes, which was specially written for publication; and which, for Forbes' own sake, I would rather not have published.

No doubt he may be annoyed by my saying that little has since been added to the observations made by Forbes on glaciers. This is a matter of opinion. I do not think that Dr. Tyndall has made any addition of consequence to our knowledge of glaciers, and I am supported in this belief by many of the very highest authorities. But this is no charge against Dr. Tyndall.

6. When I saw the "Forms of Water, &c.," I added a brief and excessively temperate statement to what I had already written, and I republished Forbes' own defence of himself against Tyndall and Agassiz. Was I not bound to do something, and could I possibly have done less?

7. The rupture of the truce, or "peace," whatever that may be, was the work of Dr. Tyndall himself—partly by his "Forms of Water, &c." mainly by his article in the *Contemporary Review*. So far as I am personally concerned, the public has no right to know my feelings:—but, whatever they are, they are mingled with the satisfaction I experience in being once more free, as of old, to point out to the public the misleading passages and actual

* Principal Forbes and his Biographers

errors in Dr. Tyndall's popular works; and to join the too thin ranks of those who, like Mr. Sedley Taylor, are not to be imposed upon by a popular reputation—but venture to think for themselves and to give the public the benefit of the result.

8. Opportunities for such public warning have never been wanting, but now they are so numerous that a long essay would be requisite to do justice to them all.

In the meantime, as an example or two, I may call attention to the way in which Sir Charles Wheatstone, and (by implication) Sir William Thomson, and others, some of whose splendid scientific labours have had the misfortune to become profitable in a pecuniary sense, are treated in Dr. Tyndall's "Lectures on Light," just published. The contrast between the utter contempt for money shown by their censor, and the (implied) opposite which is condemned as unworthy of scientific men, is brought out with all the flow of word-painting and righteous indignation which Dr. Tyndall so abundantly possesses. Besides, the monstrous doctrine is inculcated that men who devote themselves to practical applications are men incapable of original research.

9. But, to conclude for the present, I would simply call attention to the following passage, which comes from an author who in the same work treats of the relative merits of such giants as Young and Fresnel. What confidence can one have in the accuracy of any statement on a scientific matter made by the author of it?:—

"And here we may devote a moment to a question which has often been the subject of public discussion—whether, namely, a rainbow which spans a tranquil sheet of water is ever seen reflected in the water? Supposing you cut an arch out of pasteboard, of the apparent width of the rainbow, and paint upon it the colours of the bow; such a painted arch, spanning still water, would, if not too distant, undoubtedly be seen reflected in the water. The coloured rays from such an arch would be emitted in all directions, those striking the water at the proper angle, and reflected to the eye, giving the image of the arch. But the rays effective in the rainbow are emitted only in the direction fixed by the angle of 41°. Those rays, therefore, which are scattered from the drops upon the water, do not carry along with them the necessary condition of parallelism; and, hence, though the cloud on which the bow is painted may be reflected from the water, we can have no reflection of the bow itself."—"Lectures on Light," p. 25.

If Dr. Tyndall, with the assistance of his scientific advisers, fails to see the justice of my remark on this passage, perhaps you will permit me to make it the text of a little essay in a future number.

I have all along said, and still say, that I cordially recognise the services of Dr. Tyndall in popularising certain parts of Science. But his readers must be cautioned against accepting as correct great parts of what he has written. It is granted to very few men to do this useful work without thereby losing their claim to scientific authority. Dr. Tyndall has, in fact, martyred his scientific authority by deservedly winning distinction in the popular field. One learns too late that he cannot "make the best of both worlds."

I would request Dr. Tyndall for his own sake, not for mine, should he favour me with a reply, not to pick out one or two isolated passages of a letter, which absence from books may possibly have rendered slightly inaccurate—but to answer me, as he has *not* answered Forbes, in the full spirit and not in the partial letter.

P. G. Tait

St. Andrews, Aug. 20

W. S. J. on Hegel

I respectfully request admission, into an early number of Nature, for an explanatory word or two, in reference to W. S. J.'s review of my poor book on Law, &c., in the valuable publication named, for July 24, 1873.

W. S. J.'s very first sentence speaks of the said little book as containing "a discussion of Hegel's opinions concerning gravitation and the differential calculus." In the first place, Hegel has nothing to say against either gravitation as a fact, or the differential calculus as an established method of indubitable scientific calculation: he would only attempt to philosophise both by placing metaphysical principles under them. Now this is part of Newton's own action, and he certainly would not object to any *attempt*, Hegel's or other, in the same direction. In the second place, I discuss no opinion of Hegel in this reference: I only attempt to expose erroneous opinions of Hegel's relative opinions. To this I strictly confine myself, and this goes much deeper than the reader may, at first, think.

On Law, whatever is said by W. S. J., concerns only the old difficulty of Hegel's *dialectic;* and perhaps the italicising of this word, together with my own intellectual deficiences, may be respectfully offered in explanation of as much. W. S. J. here, then, is evidently misintelligent himself, and, accordingly, only speaks so as to induce misintelligence in others. Nevertheless, it is worth saying that the reader may or may not gain from the particularity of satire in W. S. J.'s hands—so keen is it that it cows, and, again, so kindly that it disconcerts.

Mathematically, according to W. S. J., "the critical statement of the necessary outcome of Hegel's philosophy," reduces itself to this, that the principle in question is placed "in that in which the quantum has disappeared, and there remains the relation only as qualitative relation of quantity." W. S. J. has for this only the mildly-authoritative contempt of a duly-elevated position; and when it is said "What is called infinitely *little* is only qualitative, and is neither little nor great, nor quantitative at all," he at once squelches all by an "*on the contrary!*" Now all this contemned matter comes directly, not from Hegel, but from Newton; for the former, quoting from the latter, says:—

"These (N.'s increments and decrements) are not to be taken as particles of a definite magnitude (*particulæ finitæ*). Such were not themselves moments, but magnitudes, generated out of moments; what is to be understood, rather, is the principles or beginnings (elements) of finite magnitude:" that is, plainly, what is concerned lies "in that in which the quantum has disappeared as quantum, and there remains the relation only as qualitative relation of quantity."

What concerns comets is naively amusing. We have not had to wait in their regard (as W. S. J. seems to think) for the information of "Chambers' Handbook." The astronomers of the last century, as it appears, were able to speak better than even the "Handbook." Comets that return, they say, though after a great many years, travel in ellipses of enormous axes; whereas those that do not return may describe parabolas or hyperbolas. Such is the opinion of Science yet, though it may talk of many other explanations of non-return, as dissipation, interception, &c. This, I say, is how Science looks yet; but W. S. J., for his part, is under the belief that Science has actually within its ken comets that (so to speak) *revolve* in hyperbolas, as well as others that revolve in ellipses. (Positively such seems his idea. Now, Hegel is never once at fault here—in his own way, I mean; for whether in ellipse, in parabola, or hyperbola, Hegel's assignation of the moment of singularity to the comet is, on his own principles, justifiable. May not a non-returning comet, too, be attributed to that contingency which is, and must be, inherent in externality as externality? On the whole, it may be well for us all to let comets alone yet. Our greatest living authority can only philosophise them into stone-rattles which the sun (for his amusement?) whirls about his head.

One has only to consider these things and others the like—the exquisite little gibes, not forgotten, about a secret in two volumes and a secret in fifteen pages, &c.—to perceive that what we have here is only once again the blind rush of prejudice from its usual dark corner of relative ignorance—an ignorance which it will persist in, and not (through study) convert into the light of day. There is that approbative allusion to Mr. Smith, too; W. S. J. will yet be ashamed of that.

On the whole, however, I hope I have not spoken disrespectfully, for I cannot fancy who W. S. J. may be. He talks of law and logic, and is possibly a lawyer; he certainly has a profound contempt for "Hegel and his satellite Stirling;" but were he (what his initials may indicate) "the eminent Jaggers" himself, I cannot, whatever his power of *practice*, admire his capacity for *principles*.

Edinburgh, July 28

J. Hutchison Stirling

Lakes with two Outfalls

In Nature, Aug. 14, a paper under this heading concludes thus:—"Colonel George Greenwood, who is, I presume, the same as the former active correspondent about this subject, visited this lake (Lesjeskaugen) last summer, as appears from the entry of his name in the day books. I am not aware that he has since published any opinion, but the lake seems, so far as I can judge, to support his view of the matter.—W. Stanley Jevons." I sent an account of my visit to Lesjeskaugen Lake

to the *Geological Magazine* in July 1872, but it was not so fortunate as to meet with acceptance from the editor. The following extracts coincide singularly with the opinions of Prof. Stanley Jevons:—

The river Rauma, at the western end, which gives its name to Romsdal, is the *natural* outlet. The outlet to the river Logen, at the eastern end, is entirely *artificial.* The water-parting there, between Romsdal and the Dovre Feld, is an ancient ridge of drift. A cut has been made by man through this ridge. The stream through this cut now works a saw mill, but was formerly connected with the old iron works. The one outlet from the lake enters the mill pool, from which there are two outlets, one to serve the mill the other for the waste water. All these three outlets are kept each at its required level *artificially*, that is, with piles, logs, boulders, and rubble, so that the quantity of water which is let out of the lake is regulated by 'the miller and his men.' The case is precisely equivalent to the Black Loch, in Dumfriesshire, whose *natural* (!) outlet is an iron sluice in a stone dam opening to a mill lead cut through the water-parting to Lord Bute's mill. (See *Athenæum*, Aug. 6, 1864, and 25 in. Ordnance maps.) If such lakes as these are lakes with two outlets, then the new conduit for the water supply of Glasgow makes Loch Katrine a lake with two outlets. An old dry channel is in direct continuation of the present mill lead. It passes so close to the old iron work as actually to touch its base. If, as I imagine (as does also Prof. Stanley Jevons), the two are connected with each other in origin, the artificial outlet to the lake may be of very great antiquity.

A notice in NATURE, of a new work by Capt. Burton (1872), quotes these words of his: "The northern and north-western portions of the so-called 'Victoria Nyanza' must be divided into three independent broads or lakes . . . *in order to account for the three effluents*, within a little more than sixty miles." Here, then, the great traveller adopts my dictum, that "a lake can only have one outlet." I first published this dictum in the *Athenæum*, July 4, 1863, when the late lamented Capt. Speke, in his "Sketch Map," gave four outlets to Lake Victoria Nyanza, three on "native information;" and in the *Athenæum*, July 25, I said, "I think that the native information will prove to be erroneous."

GEORGE GREENWOOD

Brookwood Park, Alresford, Aug. 15

As Prof. Jevons has revived the question of the existence of lakes possessing more than one outlet, I would invite the attention of your readers to what appears to me an unequivocal instance of the kind, though on a small scale, in the neighbourhood of the place whence I write.

On the high and very broken ground between the old mountain road from Dolgelly to Towyn (which runs at the foot of Cader Idris) and the south shore of the estuary of the Mawddach is a watershed, which separates streams flowing directly into the estuary by Capel Arthog from others which, after joining the stream that descends from Llyn y Gader in the hollow immediately under the summit of Cader Idris, find their way into the estuary some three miles higher up. On this watershed lies a lake about half-a-mile long, named Llyn Creigenen, which occupies a rock basin with two lips at exactly the same level, one at its western, the other at its eastern extremity. By the western lip a small stream issues which descends rapidly and at one part of its course forms one of the branches of the Falls of Arthog, well known to visitors at Barmouth. By the eastern lip also, a stream, diminutive, it is true (at any rate in the summer months), but still quite distinct, issues and descends into a boggy tract, along which it wanders for some two miles, until it joins the stream before mentioned from Llyn y Gader. These facts are distinctly recorded on the Ordnance map, and I have frequently verified them myself and pointed them out to others. I think there can be no doubt but that in this instance both of the outlets are *natural*, and that a stream must issue from one if a stream issues from the other, at any rate at the ordinary level of the water in the lake. It is perhaps, impossible to say that both outlets are *permanent* in that *secular* sense which Prof. Jevons seems to attribute to the word, as circumstances are easily conceivable under which the flow through the smaller easterly outlet might cease; but at any rate for many years, supposing the average supply of water to the lake to remain the same, and no artificial barrier to be erected, the two streams will continue to issue from the lake at all seasons.

Prof. Jevons remarks that "on *à priori* grounds it seems very unlikely that there should exist any lake with two distinct outflows." I would reply that, while it is undoubtedly improbable that any particular lake named at random should possess this characteristic, it can hardly be regarded as *à priori* very unlikely that among all the lakes on the earth's surface there should be found here and there one with more than a single outlet. At any rate, I would recommend anyone who is sceptical in the matter to visit Llyn Creigenen, which is but an easy hour's walk from the Arthog Station on the railway between Barmouth Junction and Dolgelly.

ROBERT B. HAYWARD

Capel Arthog, Aug. 16

Cranes in the Gardens of the Zoological Society of London

IN NATURE of June 26 (*antea*, p. 164), Mr. W. A. Forbes points out an error in the report of the meeting of the Zoological Society for June 15, in a statement that no example of *Grus vipio* (*sive leucauchen*) had been brought to Europe previously to those lately received by that Society. Instead of "Europe" the word "England" should have stood in the paragraph in question, which would then have been correct.

It is quite true (as stated by Mr. Forbes) that the collection of living cranes in the Gardens of the Zoological Society of Amsterdam is the finest in the world. At the same time the series of these birds in the Regent's Park is also at the present moment very nearly perfect, embracing, as it does, examples of all the usually recognised species, with the exception of *Grus leucogeranus*, and *G. monacha.*

Of the former of these the Society once possessed a living specimen, but the rare *G. monacha* of Japan has, I believe, never yet reached Europe alive.

The following is a list of the Zoological Society's present series of the Gruidæ:—2 Common Cranes (*Grus cinerea*), 1 Brown Crane (*G. canadensis*), 2 White-necked Cranes (*G. leucauchen*), 1 Sarus Crane (*G. torquata*), 1 Australian Crane (*G. australasiana*), 1 White American Crane (*G. americana*), 1 Mantchurian Crane (*G. montignesia*), 2 Wattled Cranes (*G. carunculata*), 1 Balearic Crowned Crane (*Balearica pavonina*), 4 Cape crowned Cranes (*B. regulorum*), 3 Demoiselle Cranes (*Anthropoides virgo*).

August 27 P.L.S.

Colour of Lightning

I SHOULD be much obliged to any of your readers who would give me any information as to the cause of the colour of lightning.

In one of two storms which passed over here yesterday evening the lightning was decidedly pink in tint; later in the night it had regained its normal yellow or bluish colour.

Odrey, Aug. 25 H. GEORGE FORDHAM

Harmonic Causation and Harmonic Echoes

IN reference to the question of "Harmonic Echoes," allow me to suggest to those who may have the opportunity of observation, how desirable it is that these echo-tones should be investigated in a manner to determine whether they are truly harmonic or not. There would be no difficulty in testing the sounds given in response to the notes of a closed organ-pipe and an open one, or the notes of representative musical instruments, clarionet and flute. It might be found that the echo at Bedgebury Park would give the octave always, irrespective of the particular instrument provoking it; or, on the other hand, that it refused to answer to a closed pipe, or gave only the twelfth, its proper reply. We should then know whether the echo-tone was that of the harmonic or a new fragmental tone consequent on the breaking up of the wave of the fundamental or ground-tone, by "breakers ahead."

Now that we are called upon to recognise several varieties or classes of musical tone, it is time that the leaders in Science came to a general agreement upon the use of the term "harmonic." Is it to be applied indifferently to "over-tones," otherwise "partial-tones," to "combination-tones," to "concussion-tones," arising from the violence of the shock of sound-waves in collision, to "fragmental-tones" produced out of the wave of the ground-tone broken up by obstacles encountered in its course or in reflection, and to "echo-tones" which may be affiliated to either variety? It seems to me that we risk much confusion unless "harmonic" is restricted to its earlier usage, and applied solely to the "harmonic series,"—the tones which are the direct offshoots of the fundamental. These tones have but one order of succession, and will bear no interpolation: the

octave, twice the velocity of the fundamental; the twelfth, which is three times; the fifteenth, or double octave, four times; the seventeenth, five times, and so on, always an acceleration by uniform addition. In the examples taken from the compilation of Dr. Brewer, the echo-tones go beyond all law of harmonic progression, and must be accounted for as belonging to other classes of tones, if the data can be relied upon, seeing that some instances are questionable as to authority, and others are beyond proof. The Bedgebury Park instance may be taken as proved; it is simple, and attested by living authority. Who will vouch for the other instances as evidence? The question is not put to cavil, but because of the dubiousness of the possession by the several recorders of the necessary qualification for an accurate estimate of the phenomena recorded.

Musical people of any pretension to critical power in these matters are generally "self-centered," each individual considers himself competent to pronounce judgment on "pitch," yet the delusiveness of this belief would be testified to by none more readily than by men who are daily engaged in tuning and in estimating minute relations of the invisible geometry denominated "pitch." Notwithstanding long experience and daily practice, no sooner does any question arise out of ordinary routine than they hesitate to depend on judgment alone, but resort to comparison with some fixed pitch already ascertained, and by this means prove themselves to be frequently at fault when least expecting it. Harmonic sounds are difficult to judge of, they lie at wide intervals, are frequently sharp, and if pure and faint, the ear is as liable to be deceived by an apparent lowness as it is with pure ground-tones. Fineness of ear for perception of niceties of pitch is by no means a common endowment, and where it exists, does not certify a fine musical organisation. Pitch bears relation to musical tune and to quality of tone similar to that which geometry bears to figure drawing and to painting. In rare instances only are the faculties for each associated in fair proportion, and frequently the possession of one power seems to exclude or override the others. Some men are gifted in this respect, and will tell you the pitchnote of a button, or a pencil, or a pin, as accurately as they will the notes of a song; or will discriminate, without hesitation, every note in a series of complicated chords with a skill almost as sure as instinct.

Professor Tyndall introduced the term "over-tones" in connection with "harmonic;" more recently, in Helmholtz' Lectures, Mr. Ellis has substituted "partial tones;" and Mr. Sedley Taylor adopts the same. This is a pity, for there is something incongruous in the idea of "partial tones" which yet are complete whilst component, and Tyndall's term "over-tones" is far more expressive.

The question of harmonic force, in which probably lies the explanation of the Bedgebury echo, came before me a few days since in experiments made to obviate, if possible, the wavy unsteadiness common to stopped pipes with high-cut mouths. Many variations were made without useful results. On withdrawing to some few yards' distance from the pipe into a recessed doorway, it was observable that the fundamental tone completely vanished, and the first harmonic, the twelfth, came into prominence instead of it, although you had only to step a yard forward to become again aware of the continued co-existence of the fundamental. On comparing this segregated twelfth with a corresponding note in the scale of the standard pitch of the organ, it was found to be decidedly too sharp, and thus the real cause of the waviness of tone was discovered, thereby saving many experiments in a false direction.

Several works now give elaborate analyses of harmonic tones; Mr. Sedley Taylor's "Sound and Music" is the last most useful addition, and supplies much previously wanting. In no work, however, do we meet with any definite statement as to the causation of harmonic tones; yet it seems necessary for the full understanding of their nature and of the relation they bear to the instruments producing them that the mode of their origination should not be left unheeded. The conclusion derived from my own investigations is that the harmonics of musical instruments have their origin solely in the *surplus energy* of the generating force over and above that necessary to produce the fundamental tone; this superabundant vigour finds its outlet in accessory vibrations, and the harmonics are the escape valves for securing to the fundamental tone freedom from fluctuations to which otherwise it would succumb. When the vibrating force is inadequate to waken the ground-tone of an organ pipe it settles down into the harmonic nearest related to its power; the tone may be considered as surplus energy, since it is disproportionate to its work, and only becomes harmonic because it falls short of the fundamental after which it is striving. Except in this relation we should regard it as ground-tone. When a pipe is overblown, the harmonics maintain themselves through the excess of energy to the complete exclusion of the fundamental, and they are sharp to the regulated pitch of the pipe. Harmonic tones when thus produced independently have considerably more intensity than the normal tones of pipes of corresponding pitch. In all the orchestral wind-instruments it is the higher notes that require greatest wind-force for their production; the clarionet alone differs as respects a certain range of its high notes, where the reverse is the case, the force being considerably less than for the lower range, but the structural conditions of the instrument sufficiently account for the peculiarity.

The experiment with the stopped pipe previously described clearly shows the penetrating power of accessory tones, and that whilst the fundamental occupies the ear by its volume, the harmonic has the strongest vitality even in its associated condition. In view of these facts we may reasonably infer that the "octave echo" in Bedgebury Park is the reflected harmonic heard alone; still it would be well to prove it in the manner suggested. That the voice was returned from a plantation "across a valley," gives intimation of a distance favourable to the loss of the fundamental tone in the depths of the valley; and that "the original sound required to be loud and rather high" is an additional assurance of the presence of harmonic vigour in the vocal tone.

A remarkable instance of echo freaks within my own experience is well timed to be spoken of here. At the bottom of my garden there is a meadow, then a double row of houses with a high railway embankment at the end, and a wall rising beyond that. About two months ago, whilst looking over the meadow at the clouds of sunset, the sound of a band in the distance came upon me, and, immediately following, the sound of another and more demonstrative band from an opposite direction, giving prediction of horrible discord. Strange to say, although the two bands were playing most noticeably different melodic phrases, there was no conflict; one band seemed to be the symphonic accompaniment of the other, and there was a peculiar charm in the effect, causing regret that the music should come to a natural end. Knowing that the *first* band was echo-music, there was at once a singularity to attract attention, how to account for the precedence of that which should be secondary? but the greater puzzle was to understand how it came to pass that the music was *different*, so that whilst listening the illusion of a distinct band was difficult to dispel, doubts arose about Echo having any voice in it at all, only that from time to time the pauses between the phrases showed the *following* of the form upon the shadow. Reflection upon the matter afterwards furnished the probable explanation. The distance of the place of echo was approximately between six and seven hundred feet from the source of the sounds, my standing place being at about one-fourth of the distance; between me and the band three houses intervened, over which the music came to me, whilst the terrace on which the band was stationed opened freely on to the meadow; thus Echo received the music earliest by reason of the unobstructed passage, and her rendering was that of natural selection, the most vigorous tones, and the penetrating harmonics, whatever had most living power, infused by the players and sustained by the characteristics of the instruments, all these reached her and rose again in perfect accord with the original harmony, whilst all the other notes, those of low vibrating power and of inferior stamina, were lost by the way. It should also be noted that observation afterwards of the angle of incidence and positions of the band and of the listener showed that the course of the sound waves on their way to Echo was in *front* of a detached line of cottage buildings, then passing into the enclosed space between the double row of houses up to the embankment, the recourse being by the *back* of the cottage buildings, across gardens and the meadow to the listener. Doubtless the singular vividness of the phenomena was due in great measure to the state of the atmosphere, which at the time was peculiar, the western sky heavy with gorgeous clouds, and the air silent and sultry. The relation which the organ-pipe experiment first detailed has to the theoretical solution here offered will be readily perceived; and but for the support afforded by it one could hardly have ventured on the statement and the explanation, which else would have appeared to be, the one unreal, and the other fanciful.

August 25 HERMANN SMITH

The Oreodon Remains in the Woodwardian Museum

My attention has just been accidentally called to some notes on "Oreodon Remains in the Woodwardian Museum, Cambridge" in your number of August 14.

I hasten to correct an error into which your correspondent has fallen as to the locality in which the remains to which he refers were obtained. I did not visit the Mauvaises Terres of Nebraska, but collected all my specimens in the valley of the John Day River, in Upper Oregon, about long. 120° 10′ W., lat. 44° 40′ N.

Most of the specimens are from near the head of a small stream called Bridge Creek, a locality well known to Prof. Marsh, whose new species of Oreodon described in the *American Journal of Science and Art* was possibly obtained there. A few, however, are from the Great Cañon higher up on John Day's River, nearly opposite Old Camp Watson, where I passed the winter of 1871-72.

I was informed by a gentleman who accompanied Prof. Marsh's Yale College Expedition, in October 1871, that they had on that occasion found a skull of a new and unusually large species of Oreodon in one of the places above mentioned. But your correspondent is probably acquainted with all the descriptions that have been published in America, and will know whether the *Oreodon superbus* of my informant has or has not yet been christened in print.

I have regretted much since my return that I only devoted parts of three days to a search for these interesting remains.

Walsingham

Merton Hall, Thetford, Sept. 5

Bright Shooting Stars

I beg to send you the following particulars of the observed paths of nine bright shooting stars recently seen here.

Ref. No.	Date.	Time.	Apparent Mag.	Began R.A.	Began Dec. N.	Ended R.A.	Ended Dec. N.	Length of path.	Approx. Radiant point.
		h. m.							
1	July 28	11.32	= ♃	210°	49°	200°	38°	14°	Pegasus
2	,, 28	11.48	1st mag. ✳	202	44	193½	36	10	Pegasus
3	,, 30	10 45	1st mag. ✳	42	43½	45	36	8½	χ Persei
4	Aug. 2	11.40	= ♃	43	54	62	56	12	Pegasus
5	,, 7	9.33	2 × ♀	190	59	195	30	30	Polaris
6	,, 9	10.12	= ♀	41	75	196	73	30	χ Persei
7	,, 9	10.29	1st mag. ✳	37	45	50	42	10	Andromeda
8	,, 9	11.25	1st mag. ✳	337	59	304	50	20	χ Persei
9	,, 9	11 29	1st mag. ✳	28	41	12	46	12	Andromeda

No. 5 in the above list was the brightest, and left a very perceptible train just N. of Cor. Caroli for 7^s. No. 9 also left a train, visible for 3^s, N. of γ Andromedæ.

The evening of August 9 was clear, and two observers counted thirty-five meteors in the interval between 10h. 15m. and 11h. 45m., after which time clouds obscured the sky. During the night of August 10 it remained overcast. Of the thirty-five shooting stars seen on August 9, the great majority were Perseïds, but the radiant region is diffusely extended from the star group at χ Persei to B Camelopardali. There were also indications of radiation from Pegasus and Andromeda. The August meteors of this year appear to have been larger than those seen in former years; at any rate bright meteors have been exceptionally abundant during the dates included in the above list.

William F. Denning

Bristol, August 11

November Meteor Shower of 1872

Mr. E. D. Jones, of San Paulo, Brazil, has sent me the enclosed extract from his diary, referring to the meteor shower of November last, which he observed whilst crossing the Atlantic.

Henry C. Beasley

Gateacre, Liverpool, Sept. 3

"Nov. 27, 1872, s.s. *Halley*, N. lat. 11° 30′, W. long. 26° 50′.—There was a splendid shower of meteors this evening. I saw them shooting in profusion as soon as it was dark (about half-past six). I sat in a chair on deck facing the west, where Jupiter was flaring in the tropic sky, and watched the flying messengers from other worlds. I counted no less than 400 in half an hour, that is at the rate of about 14 per minute. They came in shoals, as it were. There would be a long pause, and then five or six would fly across together, reminding me forcibly of the flying-fish we had seen in the daytime. Every now and then a much brighter one than usual would flash into existence, and leave a trail of beautiful reddish light behind. Generally speaking, they were as bright as a star of the second magnitude. But the brighter ones I speak of were quite equal to stars of the first magnitude. One splendid one at about eight o'clock (local time) was so bright that it lit up the sails of the ship; it was of a red colour, and burst in two before disappearing. One later on left a trail which I could distinguish for half a minute. I was able to trace the point in the heavens from which the meteors emanated, viz., a point near the northern extremity of Perseus, between that constellation and Andromeda. About this point I often saw them come into view, and die away with scarcely any apparent motion, on account of their coming in a straight line towards the observer; below this point they fell towards the horizon, above it they fell across the zenith, and so on. Those with the longest path were in the western sky (opposite Perseus), as the view was the least fore-shortened there. The position of the *Halley* was that given at the heading of this extract. The following table shows that we probably did not see the thick of the shower, having passed it by daylight:—

G.M.T.	Time in which 100 were seen.	Number per minute.
8.30 P.M.	8 minutes	12·5
8.38 ,,	7 ,,	14·3
8.45 ,,	7 ,,	14·3
10.5 ,,	17 ,,	5·9
10.22 ,,	17 ,,	5·9
10.49 ,,	22 ,,	4·6
12.15 A.M.	36 ,,	2·8

"The reasons that the first observation gives fewer than the second, may be that the twilight did not allow of the less brilliant meteors being seen; that the eye of the observer was not so well practised in detecting them; and the light clouds flying through the air may have obscured some of them. The other observations show a regular decrease in the numbers from 8·45 P.M.

"I counted 750 meteors in my observations, and saw quantities more besides. Of course I could only see about one-third of the sky at a time, but I was looking in the direction of the thickest fall most of the time, so that I daresay I saw half the number that actually fell; taking this for granted, there must have been 3,500 between 8.30 P.M. and 12.15 A.M., Greenwich mean time."

EXPLORATIONS IN THE GREAT WEST

We are now in possession of facts which will supplement our last reference to this subject. The following names may be added to the list of scientific men accompanying the Wheeler Expedition engaged on surveys west of the 100th meridian:—Mr. Severance, ethnologist; Drs. H. C. Garrow and J. L. Rothock, naturalists; Mr. H. Stewart Brown, meteorologist; Messrs. Klett and Louis Mell, topographers. The entire force numbers 175 men.

The surveying party of Mr. Clarence King, geologist, designated as the Geological Survey of the 40th parallel, has just finished its work and is recently disbanded. Among the scientific men accompanying it were Messrs. J. G. Gardner (astronomer and geographer), Wilson (topographer), J. D. Hague (mining geologist), Emmons (assistant geologist), Arnold Hague (chemist and mineralogist), Robert Ridgway (zoologist), and S. Watson (botanist). The force is largely absorbed by other expeditions now in the field. The results of this expedition are expected to fill five quarto volumes and accompanying atlases; of which one on mining in Nevada and adjacent territories with folio atlas will be by Mr. Hague, and one on botany is already published. The remaining volumes are well under way and will, it is expected, be completed during the present year.

There is an expedition known as the International

Northern Boundary Commission, engaged in the survey of the 49th parallel from the Lake of the Woods to the crest of the Rocky Mountains. Archibald Campbell, of Washington, is the commissioner in charge; Major Twining is the chief of engineers on the part of the United States, and Dr. Elliott Coues of the U.S. army is the naturalist of the expedition. The British Government details its proportion of the party, which is thoroughly equipped for this service. The operations of the present year extend westward from Pembina.

The expedition under Major J. Powell, to the cañons of Colorado, is still in the field. Major Powell has spent several years in explorations in this region, and has constructed a map of great interest and accuracy. His ethnological researches among the Piute and other Indian tribes have resulted in a large and exceedingly valuable collection.

Mr. Wm. H. Dall, well known by his elaborate work on the Territory of Alaska, founded on his former three years' residence in that region, is now actively employed in continuing his survey and hydrography in the Aleutian Islands, under the direction of the U.S. Coast Survey, a work on which he has been engaged during the past two years. His labours have been principally in Alaska and the adjacent islands, from which he returned last September, having gone there in the summer of 1871. He spent last winter in San Francisco, in preparing for the expedition of the present year, which included fitting out a vessel expressly for this service. Among other objects contemplated is the selection of an island on the western extremity of the Aleutian chain, to serve for the landing of the Japan cable, for laying which the U.S. steamer *Narragansett* has been detailed to make deep-sea soundings. Mr. Dall is assisted by Prof. Baker, of Ann Arbor, Mich., astronomer.

Mr. Henry W. Elliott is at the head of a private expedition to St. Paul and St. George, the fur-bearing seal islands of Bering's Sea. He has the assistance of Captain Bryant, who is in charge of the U.S. Revenue and other Government interests on these islands. Mr. Elliott is making exhaustive collections in natural history, which he sends to the National Museum at Washington, his investigations respecting seals and walruses being especially valuable and complete. His labours during 1872 were demonstrated by twenty large boxes of collections. He is a very skilful draughtsman, and his drawings of natural subjects are remarkable alike for accuracy and vigour.

ON THE SCIENCE OF WEIGHING AND MEASURING, AND THE STANDARDS OF WEIGHT AND MEASURE *

V.

IV.—*The Metric System*

As a system of weights and measures, constructed on strictly scientific principles, the metric system may justly claim pre-eminence over all others. It was established upon the fundamental basis of the *metre*, its primary unit of length bearing a determinate decimal ratio to one of the largest natural constants, that is to say, the ten-millionth part of the earth's meridian-quadrant. It includes a fixed relation between the units of weight and capacity, the *kilogramme* and the *litre*, and the unit of length, the *metre*, from which both are derived; and it comprehends a uniform decimal scale of multiples and parts of these units. It must, however, be admitted that the more recent progress of modern science has demonstrated that the actual standards of metric length, weight, and capacity do not exactly correspond with their scientific definition; and apart from the insuperable difficulties which have been found to exist in the precise determination of material standards from any natural constant, the unanimous opinion of several of the highest scientific authorities in this country has been deliberately expressed that there is no practical advantage in adopting a unit founded in nature over one of an arbitrary character. In truth, the great advantage of the metric system consists in the simplicity and uniformity of its decimal scale, and the great convenience of this scale for all purposes of account as agreeing with the decimal system of notation, and more especially when combined with a decimal coinage which formed part of the original scheme. These undoubted advantages have proved the chief recommendations to the adoption of the metric system, first by France, and afterwards by so many other countries, and generally in the scientific world. There is now every prospect of the metric system being generally adopted in all countries of the civilised world, thus greatly enhancing its value as a common international system of weights and measures, and constituting, as it were, a universal language for expressing all quantities weighed or measured.

The original steps which led to the establishment of the metric system in France were taken with a view of reforming the old French system of weights and measures, which had become intolerable from their defective state and want of uniformity. In 1790, on the motion of M. Talleyrand, in the National Assembly, the question o the formation of an improved system to be based upon a natural constant, was referred to the French Academy of Sciences. A request was also made at the same time to the British Government that the Royal Society should act jointly with the French Academy, but no response was given to the invitation, in consequence of the distrust then entertained in this country at the progress of the revolutionary party in France. The preliminary work was consequently entrusted to five of the most eminent members of the French Academy, Lagrange, Laplace, Borda, Monge, and Condorcet. The important Report of this Committee, which bears also the signature of a sixth member, Lalande, gave rise to the metric system. It was presented to the Academy on March 19, 1791, and is printed at length in their Memoirs. The choice of the fundamental unit of the new system lay in its derivation either from the length of the seconds-pendulum, of the earth's equator, or of the earth's meridian. The Committee rejected the length of the pendulum beating seconds as the basis of the new standard unit of length, because it involved a heterogeneous element, that of time, as well as an arbitrary element, the division of the day into 86,400 seconds. They proposed a unit of length taken from the dimensions of the earth itself, and not dependent upon any other quantity; and they did not hesitate to select as its basis the quadrant of the meridian in preference to a quadrant of the equator, from its being a universal measure applicable to all countries, as every country was placed under one of the meridians of the earth, whilst only few countries are under the equator. They considered also that no greater dependence could be placed upon the regularity of the equator, than upon the equality or regularity of the several meridians. They recommended the ten-millionth part of the quadrant of the meridian as the definition of the new fundamental unit of length. Renouncing the ordinary subdivision of the meridian-quadrant into degrees, minutes, and seconds, they proposed a uniform decimal scale as practically the best, from its agreeing with the scale of arithmetical notation. In order that no other arbitrary principle should be introduced into the new system of weights and measures, they recommended for the basis of the unit of weight a measured quantity of distilled water, being a homogeneous substance, always to be easily found in the same degree of purity and density; and that such quantity should be weighed in a vacuum at its temperature when passing from a solid to a liquid state.

* Continued from p. 370.

For the practical purpose of ascertaining the length of the meridian quadrant, they proposed to measure an arc of the meridian from Dunkirk to Barcelona, a distance of nearly 9½°, and comprehending about 6° to the north and 3½° to the south of the mean parallel of latitude. These extreme points had also the advantage of being both at the sea level. The actual operations required were stated to be as follows :—

1. To determine the difference of latitude between Dunkirk and Barcelona.

2. To re-measure the ancient bases which had served for the measurement of a degree at the latitude of Paris, and for making the map of France.

3. To verify by new observations the series of triangles employed for measuring the meridian, and to prolong them as far as Barcelona.

4. To make observations in lat. 45° for determining the number of vibrations in a day, and in a vacuum at the sea level, of a simple pendulum equal in length when at the temperature of melting ice, to the ten-millionth part of the meridian quadrant, with a view to the possibility of restoring the length of the new standard unit, at any future time, by pendulum observations.

5. To verify carefully and by new experiments the weight in a vacuum of a given volume of distilled water, at the temperature of melting ice.

6. To draw up tables of existing measures of length, surface, and capacity, and of the different weights in use, in order to ascertain their equivalents in the measures and weights of the new system, as soon as they should be determined.

In pursuance of the recommendations of this Report, the law of March 26, 1791, was passed by the National Assembly for constructing the new system upon the proposed basis ; and the Academy of Sciences was charged with the direction of the necessary operations. They entrusted the measurement of the arc of the meridian from Dunkirk to Barcelona to two of their members, Méchain and Delambre, who carried on the work during seven years, from 1791 to 1798, notwithstanding many great difficulties and dangers.

The unit of measure adopted for the actual measurement was the existing French standard of length, the Toise of the Academy, better known as the *Toise de Perou*, a measure of 6 French feet (*Pieds du Roi*). This standard is now deposited at the Observatoire at Paris. It is a bar of polished iron, about 1½ inch in breadth, and ⅓ inch in thickness, and a little longer than a toise. The length of a toise is marked by a rectangular step near each end of the bar, leaving the remaining portion at the ends half the thickness of the measuring part of the bar.

The true length of the toise was taken about a line (or $\frac{1}{12}$ inch) above the re-entering angles of the bar, at the temperature of 13° Réaumur, or 16°·25 C. It has been declared to be equal to 76·7563 English inches, the old French foot (which was divided into 12 inches and the inch into 12 lines), being equal to 12·792 English inches. The toise was afterwards found to be equal to 1·94904 metre.

This standard had been originally constructed as the unit for measuring an arc of the meridian in Peru, and for verifying the meridian of Paris, in 1740 ; and it was substituted in 1766 for the more ancient French standard of length, the *Toise du Grand Chatelet*, from which it had been originally derived. This older toise was deemed wanting in the scientific precision requisite for a standard of length. It had been constructed in 1668, and is said to have been 5 lines shorter than the toise measure then ordinarily used, for which no authoritative standard could be found ; and to have been actually derived from the width of the inner gate of the entrance to the Louvre, which, according to the original plan, was made 12 feet wide, and one half of this width was taken for the length of the standard toise.

The measures actually used for the survey operations are known as the *Règles de Borda*. They were four in number, each consisting of a bar of platinum two toises, or 12 French feet, in length, about ½ inch broad, and $\frac{1}{12}$ inch thick. Each platinum bar was fixed at one end only to a bar of brass about 11½ feet long, the other end of the platinum bar being free and extending about 6 inches beyond the corresponding end of the brass bar. The object of this second bar was that it should form, together with the first bar, a metallic thermometer, indicating the temperature of the two bars by their difference of dilatation, which could be measured by a fine vernier. The four measuring bars were accurately verified, and found, when placed together, end to end, not sensibly to differ from eight times the length of the Toise of Peru at the temperature of 12°·5 C.

The base for the measurement of the northern portion of the work was measured at Melun, and found to be 6075·90 toises. The base for the southern portion was measured at Perpignan, and found to be 6006·25 toises.

Meanwhile the Academy of Sciences was abolished in 1793, by a decree of the National Convention, and a Commission of eleven scientific men, consisting principally of those who had been previously engaged in the proceedings, was appointed, in 1795, to carry out all the arrangements for the definitive establishment of the Metric System. In 1798, towards the close of the operations, an equal number of scientific men, representatives of foreign countries, were added to the Commission, which was then composed as follows :—

French Members : MM. Borda, Brisson, Coulomb, Darcet, Delambre, Lagrange, Laplace, Lefevre-Gineau, Legendre, Méchain, de Prony.
From the Batavian Republic : Aeneae, Van Swinden.
Sardinia : Balbo, afterwards replaced by Vassali, from the Provisional Government of Piedmont.
Denmark : Bugge.
Spain : Pédrayés, Ciscar.
Tuscany : Fabbroni.
Roman Republic : Franchini.
Cisalpine Republic : Mascheroni.
Ligurian Republic : Multedo.
Helvetian Republic : Trallès.

The final results of all the operations for determining the new metric unit of length, were stated by the Commission in their Report, dated April 30, 1799. They found :—

1. That the length of the arc of the meridian comprehended between Dunkirk and Barcelona, was 9·6738° (or 9° 40′ 45″), and measured 551,584·72 toises.

2. Assuming, from the previous measurements in France and Peru, that the mean ellipticity of the earth was $\frac{1}{334}$, they computed the length of the meridian-quadrant to be 5,130,740 toises.

3. That the length of the new unit of length, the ten-millionth part of the meridian-quadrant, was equal to 0·5130740740 toise, or 3 feet and 11·296 lines; being 443·296 lines of the Toise of Peru (which contained 864 lines), at its standard temperature of 16°·25 C. In terms of the new standard unit, the Toise of Peru was equal to 1·949036591 metre.

4. That the length of the pendulum at the temperature of melting ice, beating seconds in a vacuum at the sea level at Paris, was equal to 0·99385 metre.

The actual construction of the new standard measure of length had been entrusted to the mechanician Lenoir. As a preliminary proceeding, he made four end-standard metres of brass, differing in length very slightly from each other, and each about equal to 443·242 lines of the Toise of Peru. This was the computed length of one ten-millionth part of the meridian-quadrant, as deduced from the previous measurements of an arc of the meridian in France made in 1740. The length of these four brass metres, when placed end to end, was nearly 1,773 lines,

thus exceding double the length of the Toise of Peru, by about 45 lines. Lenoir constructed a supplementary measure of this excess of length, and its exact relation to the toise was ascertained by numerous comparisons, for which other intermediate measures were employed, and their exact length determined. The actual comparisons of the four brass metres were made not with the Toise of Peru itself, but with two standard toises constructed by Lenoir, the length of each of which in relation to the Toise of Peru had been carefully determined. In these comparisons the additional length of the measure of 45 lines was also employed. The comparing instrument was a *comparateur* made by Lenoir, which enabled very minute differences in measuring bars under comparison to be read off on a subdivided scale by means of a contact lever. One division of this scale was equal to 0·00001 toise, and one-tenth part of one of these divisions (= 0·001949 mm.) could be read off with the aid of a vernier. It appears from the Report of MM. Borda and Brisson, dated July 17, 1795, that the result of a number of comparisons, including those of the four metres with each other, showed metre No. 2 to be nearest to the required length, being 443·4519 lines of the Toise of Peru at the mean temperature during the observations of 12°·96 Réaumur, thus very closely approaching its standard temperature of 13° Réaumur, and exceeding the required length at this temperature by only 0·0119 line. It was accordingly selected as the provisional Standard Metre. But they considered that its standard temperature would more conveniently be fixed at 10° C., and as, according to Borda's determination, the coefficient of dilatation of brass between 0° and 32° C, was 0·00001783 for 1° C. they determined its length at 10° C. to be 443·401 lines of the Toise of Peru.

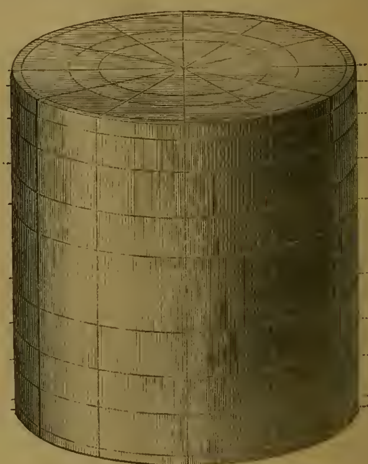
For obtaining the definitive standard, which was to be the length of 443·296 lines of the Toise of Peru at 16·°25 C., which was thus so nearly indicated by the provisional metre, two standard metres of platinum, and twelve metres of iron, were constructed by Lenoir, his comparing apparatus having been improved so as to show differences of 0·001 line. The Commission were not satisfied with making numerous comparisons of these metres and the provisional metre of brass among themselves, but they also compared them repeatedly with the four *Règles de Borda* and a new supplementary measure of above 45 lines, so as to determine not only their relative and absolute length, but also the rates of expansion of the three metals of which they were composed. The rates of expansion definitively adopted by the Commission, from observations made by Borda between 0° and 32° C., were as follows :—

			In a metre.
Coefficient of linear expansion of	platinum	for 1° C. = 0·00000856,	or 0·0031 mm.
,,	brass	,, = 0·00001783,	or 0·0092 ,,
,,	iron	,, = 0·00001156,	or 0.0063 ,,

The comparisons and corrections of the several metres were continued until no difference amounting to 0·000001 toise, or 0·001 millimetre, could be found at the temperature of melting ice, either in their desired absolute length of 443·296 lines of the Toise of Peru or in relation to each other. They were consequently all determined to be perfectly exact. One of the platinum metres, subsequently known as the *Metre des Archives*, from its place of deposit, was reserved as the new prototype measure of length ; the other was kept at the Observatoire at Paris, as its accessible representative. The twelve iron standard metres were distributed amongst the several countries represented at the Commission.

The primary *Metre des Archives* is a rectangular platinum bar, bearing no mark or description. Its breadth is 25 mm. (0·984 in.), its height 3·5 mm. (0.138 in.). Its ends are planes perpendicular to its axis of length, and the straight line between them in this axis denotes the true length of the metre at 0° C., or the temperature of melting ice. It thus constitutes what is termed a *Mètre-à-bouts*, or end-standard metre.

The unit of metric weight was defined to be the weight in a vacuum of a cubic decimetre of distilled water at its maximum density, or the temperature of 4° C. Distilled water was selected as the best material in nature for thus determining the unit of weight, from its being obtainable everywhere and at all hours in the greatest purity, its being perfectly homogeneous, and its density being invariable at any given temperature. It was required first accurately to ascertain the weight of this volume of water, and then to construct a metallic standard of equivalent weight. The necessary operations for effecting both these objects were entrusted to M. Lefevre-Gineau in 1795. He had to decide between two modes of proceeding for accurately determining the volume of water to be weighed ; one, by measuring the internal capacity of a vessel to contain this volume of water ; the other, by measuring externally a solid or hollow body, in order to ascertain the weight of the volume of water displaced by it. He chose this last method, considering that the accurate external measurement of a metallic body was much less difficult than that of the internal capacity of a metallic vessel ; and it was determined that the best form of this body was a cylinder of a height equal to the diameter of the base, this form



IG. 10.—Cylinder for determining cubic centimetre.

being capable of being made and measured with the greatest precision.

It was not thought requisite that the cylinder should be of the specified volume of a cubic decimetre, but only of the most convenient size for arriving at the desired result by computation. The cylinder actually used was made of brass, and hollow, being only so much heavier than the same bulk of water as to enable it to sink by its own weight when plunged in water. It was intended to be 2·435 decimetres (about 9½ inches) in diameter and height.

To facilitate the accurate measurement of the cylinder, 12 radial lines or 6 diameters were drawn on its base plane, dividing it into twelve equal parts ; and corresponding lines were drawn on its upper plane. The ends of these two series of lines at the circumference were joined by vertical lines on the cylinder, thus dividing it vertically into twelve equal parts. Circular lines were also traced on the two plane surfaces at about 11 mm. from the circumference, and at half and two-thirds of the radius from the centre ; and eight horizontal lines were

drawn around the cylinder at the following distances from the base:—13, 35, 67, 95, 148·5, 176·5, 208·5, 230·5 millimetres. The height of the cylinder was determined from the ascertained mean distance of the corresponding 37 points of intersection of the lines on the upper and lower surfaces, including the centres. The diameter of the cylinder was determined from the ascertained mean length of the 48 diameters, included between the corresponding points of intersection on its cylindrical portion.

The measurement was effected by means of an apparatus specially constructed for the purpose by Fortin, and it indicated minute differences of length of $\frac{1}{4000}$ line, or $\frac{1}{1700}$ mm.. The standard measures used for determining the absolute length measured were 16 brass measures specially constructed for the purpose, each very nearly equivalent to the height of the cylinder, and 16 other measures, each nearly equivalent to its diameter. The length of each of these two series of measures in relation to each other was ascertained by numerous observations with the new apparatus; and the total length of each set of 16 measures in relation to the new standard unit was obtained by comparing the sum of their length with Borda's *règle* of 2 toises, No. 1, to which they very nearly corresponded in length, by means of the *comparateur* used for the comparison of these large measuring rules.

The final result of the measuring operations was that the mean height of the cylinder was determined to be 2·437672 decimetres, and its mean diameter 2·428368 decimeters, at the temperature of 17°·6 C. According to Borda's determination of the coefficient of the linear expansion of brass, the volume of the cylinder was determined by computation to be nearly 11·28 cubic decimetres, when at the temperature of melting ice.

For ascertaining the weight of water displaced by this cylinder, a series of brass weights was specially constructed, consisting of a unit or provisional kilogram, made as nearly as possible of the estimated weight of a cubic decimetre of water, together with 11 exact copies and smaller weights in decimal subdivision down to the millionth part, all carefully verified and deemed to be accurate within less than half of one-millionth part.

The mean weight of the cylinder in ordinary air was taken, no reduction to a vacuum being deemed requisite, as the weights used were of similar metal to the cylinder, the interior of which communicated with the external air. For this purpose a metallic tube, 1·285 mm. in diameter, was screwed to the top of the cylinder, its end being out of the water when the cylinder was immersed. The top of the cylinder was 43 mm. from the surface of the water during the weighings, and the volume of the tube immersed was therefore 55·77 cubic mm. Taking the volume of the cylinder to be 11·28 cubic decimetres, the volume of the metallic part of the cylinder was computed to be 1·506 cub. decim., and of the hollow part filled with air 9·774 cub. decim. During the weighings the cylinder was surrounded with ice, but the temperature of the water was never below 0°·2 C. and the mean temperature was 0°·3. The final results of the weighings were declared to be as follows:—

	Prov. kilo.
Weight of the cylinder in air, in terms of the unit employed	= 11·4660055
Its mean weight in distilled water, after deducting the weight of air in the cylinder, and of the air displaced by the weights used	= 0·1967668
Hence weight of the volume of distilled water equal to the volume of the cylinder	= 11·2692387

H. W. CHISHOLM

(*To be continued.*)

NOTES

It is announced that the Transatlantic Balloon will leave New York to-day. It will carry four passengers—Prof. Wise and Mr. Donaldson, the aëronauts; an officer of the United States Signal Service, and an agent of the *Daily Graphic*. They hope to reach some point on the English or Continental coast in about sixty hours from their departure from New York. They have with them six very powerful and experienced carrier-pigeons, purchased in Belgium, which, if liberated from the balloon within "pigeon flight" of the coast, are expected to fly directly to their old homes. Each of these has painted on his breast, in indelible ink, the outline of a balloon, and on his wings the words, "Send news attached to the nearest newspaper." Despatches received by these pigeons should be sent to the nearest newspaper for publication. We wish these daring men a safe landing; but while we do this we regard the enterprise as one needlessly hazardous, so far as the settlement of the scientific problem is concerned.

Mr. Campbell, the Chief Secretary of the Inspectorate-General of Customs in China, is now in Europe with a view of obtaining instruments for a complete chain of meteorological stations in that country. It is also proposed to transmit weather information all along the east coast of Asia. This is great news, and we shall return to this important matter, giving full details of the proposals.

Miss Elizabeth Thompson, of New York, has made a donation to the American Association for the Advancement of Science of 1,000 dols., for the purpose of advancing scientific original research; and she intends repeating the donation annually during her life.

M. Stephan has succeeded in finding Faye's Comet. The correction of the Jahrbuch Ephemeris is almost *nil*.

Mr. Froude, who is now with the *Devastation*, informs us that it is Mr. W. Barlow, not himself, who is president of Section G at the ensuing meeting of the British Association. Mr. Froude will, indeed, probably not even be able to attend the Bradford meeting at all.

We learn from the *Monthly Microscopical Journal* that Prof. Gegenbauer, of Jena, the well-known comparative anatomist, has been nominated Professor of Anatomy and Director of the Anatomical Institute in the University of Heidelberg.

The arrangement made by Prof. Henry, of the Smithsonian Institution, a few months ago, for the interchange between America and Europe, by Atlantic cable, of important astronomical discoveries and announcements, appears to have borne excellent fruit. One great object of this movement was to enable astronomers in all parts of the world to concentrate attention upon any celestial phenomenon before too great a change of place had occurred, or before the intervention of a long period of moonlight after the first discovery. On the 26th of May last Prof. Henry announced a new planet, discovered by Prof. Peters, to the Observatory of Paris, among other institutions, and on the following night it was looked for by the director of the Observatory of Marseilles, who at once detected it, and subjected it to a careful criticism. The announcement of three planets has thus far been made from the Smithsonian Institution to Europe; the only return communication being that of a telescopic comet, discovered at Vienna on July 5. On being notified of the fact, Prof. Hough, of the Dudley Observatory at Albany, made search for it, and succeeded in finding the object without any difficulty.

Biology is flourishing at the Antipodes. The last mail has brought us "Australian Vertebrata, fossil and recent," by G. Krefft, curator and secretary of the Australian Museum, Sidney; a list of Australian Longicorns, chiefly described and arranged by Francis P. Pascoe, with additional remarks by George Masters, assistant curator of the Australian Museum; Guide to the

Australian Fossil Remains exhibited by the trustees of the Australian Museum, by G. Krefft, curator and secretary; a Catalogue of the Marine Mollusca of New Zealand, by Capt. F. W. Hutton, assistant geologist; and a paper on the Geographical Relations of the New Zealand Fauna, by the same.

We have received from the Science and Art Department the following list of Queen's Medallists in the Science Examination, May 1873; we regret that want of space compels us to give only the gold and silver medallists.—Practical Plane and Solid Geometry: Atkinson, Roger, Crewe Mech. Inst., gold; Millington, F. H., Patricoft Mech. In., silver.—Machine Construction and Drawing: Daltry, Thomas L., Newcastle, Elswick Mech. In., gold; Atkinson, Roger, Crewe Mech. In., silver.—Mathematics: McAlister, Donald, Liverpool In., gold; Edwards, Harry H., Liverpool In., silver.—Theoretical Mechanics: McAlister, Donald, Liverpool In., gold; Sisson, William, Newcastle Mech. In., silver.—Applied Mechanics: Millington, Fred H., Paticroft Mech. In., gold (obtained gold medal in 1872); Dixon, Samuel, Manchester Mech. In., gold; Daltry, Thomas L., Newcastle, Elswick Mech. In., silver.—Acoustics, Light, and Heat: Martin, T. W., Newton Abbott, gold; McAlister, D., Liverpool Inst., silver.—Magnetism and Electricity: McAlister, Donald, Liverpool Inst., gold; Louis, Henry, Islington Sci. and Art Sch., silver.—Organic Chemistry: Whiteley, John, Halifax W. M. Coll., gold; Taylor, William D., Belfast, W. M. Inst., silver.—Geology: Dowlen, Ethelbert, Woking, St. John's, gold; Southeran, Arthur, Marske Inst., silver.—Vegetable Anatomy and Physiology: Dowlen, E., Guildford Science, silver.—Navigation: Windass, John T., Hull Nav. Sch., gold; Daws, Thomas, Plymouth, Courtenay Street Sch., silver.—Nautical Astronomy: Lawson, Henry, Hull Nav. Sch., silver (obtained silver medal in 1872); Ashford, Joseph, Hull Nav. Sch., silver.—Steam: Fairweather, James, Glasgow, Anderson Univ., gold; Daltry, Thomas L., Newcastle, Elswick Mech. Inst., silver.—Physical Geography: Forbes, James L., Torphins Sci. Sch., gold; Armstrong, J. W., Blackburn School of Science and Art, silver.

Mr. J. Wood-Mason, of Queen's College, Oxford, is to officiate as Professor of Comparative Anatomy and Curator of the Comparative Anatomy Section of the Medical College Museum, Calcutta, during the absence, on furlough, of Dr. J. Anderson.

Messrs. Longmans announce the following among their forthcoming scientific publications:—A new volume of Transatlantic Travel, entitled "The Atlantic to the Pacific; What to See, and How to See it," by John Erastus Lester, M.A., author of "The Yo-Semite, its History, Scenery, and Development." A study of Asiatic savage life, entitled "A Phrenologist amongst the Todas, or the Study of a Primitive Tribe in South India—History, Character, Customs, Religion, Infanticide, Polyandry, Language," by William E. Marshall, Lieut.-Col. of H.M. Bengal Staff Corps. A second Supplement to Watts's "Dictionary of Chemistry." The first Supplement, bringing the record of chemical discovery down to the end of the year 1869, was published in 1871. The second Supplement, now in course of preparation, is intended to bring the record of discovery down to the end of 1872, including also the more important additions to the science published in the early part of 1873. This Supplement will form a volume of about 800 pages, and is expected to be ready in the year 1874. The author has been fortunate in securing the co-operation of several of his former contributors. A new work on "Sidereal Astronomy," by R. A. Proctor. "Introduction to Experimental Physics, Theoretical and Practical, including Directions for Constructing Physical Apparatus and for Making Experiments," by Adolf F. Weinhold, Professor in the Royal Technical School at Chemnitz, translated and edited (with the author's sanction) by Benjamin Loewy, F.R.A.S., with a Preface by G. C. Foster, F.R.S., Professor of Physics in University College, London. "A Treatise on Practical, Solid, or Descriptive Geometry, embracing Orthographic Projection and Perspective or Radial Projection," by W. T. Pierce, Architect, late Lecturer on Geometrical Drawing at King's College, London, and at Harrow School. "On the Sensations of Tone, as a Physiological Basis for the Theory of Music," by H. Helmholtz, Professor of Physiology, formerly in the University of Heidelberg, and now in the University of Berlin, translated from the third German Edition by Alexander J. Ellis, F.R.S., formerly Scholar of Trinity College, Cambridge. "Organic Chemistry," by H. E. Armstrong, Ph.D., Professor of Chemistry in the London Institution: "A Manual of Qualitative Analysis and Laboratory Practice," by T. E. Thorpe, F.R.S.E., Professor of Chemistry in the Andersonian University, Glasgow, and M. M. Pattison Muir; "Telegraphy," by W. H. Preece, C.E., Divisional Engineer Post Office Telegraphs, and J. Sivewright, MA., Superintendent (Engineering Department) Post Office Telegraphs; "Elements of Machine Design, with Rules and Tables for designing and drawing the Details of Machinery," adapted to the use of Mechanical Draughtsmen and Teachers of Machine Drawing, by W. Cawthorne Unwin, B.Sc. Assoc. Inst., C.E., Professor of Hydraulic and Mechanical Engineering at Cooper's Hill College; "Principles of Mechanics," by T. M. Goodeve, M.A., Lecturer on Applied Mechanics at the Royal School of Mines, and formerly Professor of Natural Philosophy in King's College, London. These five works form part of the series of text-books now being published by the Messrs. Longmans.

Among Messrs. Macmillan's announcements of forthcoming works are—"On the Theory of Sound," by Lord Rayleigh, F.R.S.; "Contributions to Solar Physics," by J. Norman Lockyer, F.R.S., with numerous illustrations; "Cave Hunting," by W. Boyd Dawkins, F.R.S., being researches on the evidence of caves respecting the early inhabitants of Europe; "The Origin and Metamorphoses of Insects," by Sir John Lubbock, F.R.S. (vol. ii. Nature Series); and a new edition of Canon Kingsley's "Glaucus."

During the ensuing season Messrs. H. S. King and Co. will publish the following new volumes of their "International Scientific Series":—"Mind and Body," by Alex. Bain, LL.D.; "Animal Mechanics," by J. Bell Pettigrew, M.D., F.R.S.; "Principles of Mental Physiology," by W. B. Carpenter, LL.D., F.R.S.; "On the Conservation of Energy," by Prof. Balfour Stewart; "The Animal Machine, or, Aërial and Terrestrial Locomotion," by Prof. C. J. Marey; "The Study of Sociology," by Herbert Spencer. With the exception of the last-named work, the whole of the above will be illustrated.—Messrs. H. S. King and Co. also announce the following books of interest to scientific men:—"Studies of Blast-furnace Phenomena," by M. L. Gruner, translated by L. D. B. Gordon; "The Norman People and their Existing Descendants in the British Dominions and the United States of America," and "The History of the Natural Creation," a series of popular Scientific Lectures on the Theories of Progression of Species, by Prof. Ernst Hæckel.

Mr. Van Voorst has recently published new editions of "Blackwall's Researches in Zoology, illustrative of the Structure, Habits, and Economy of Animals," and Salvin and Brodrick's "Falconry in the British Isles."

Prof. E. D. Cope has been bold enough, in the August number of the *Penn Monthly* (Philadelphia), to portray his conception of the general external appearance of the new gigantic mammal from Wyoming, named *Tinoceras anceps* by Marsh, and *Loxolophodon cornutus* by himself. The result is an elephantine form, with elephantine knees, feet, ears, and tail; bovine preputial sheath; and a head with two pairs of somewhat cervine horns, and an anterior pair of simple but diverging processes. A proboscis about half as long as the head is made to project for-

wards in a Tapir-like manner, below the base of which the upper canines descend in a way which shows that it would be impossible to use them for defence or obtaining food, without doing great injury to the sensitive trunk which overshadows them. Nothing seems more illogical than the assumption, that because an animal has elephantine proportions and feet, it should possess a proboscis, especially when all arguments from the skull tend in a different direction.

THE Quarterly Weather Report, from July to September, contains, in addition to the usual tabular results, a discussion of four years anemometrical results for Bermuda.

WE have received the Report on the Freshwater Fish and Fisheries of India and Burmah, by Surgeon-Major Francis Day, Inspector-General of Fisheries in India.

WE have received from Prof. Edward Morse an excellent paper, read by him before the Boston Society of Natural History, on the Systematic Position of the Brachiopoda, in which, from a careful study of the anatomy and development of those animals, he has been led to endorse and substantiate Steenstrup's opinion as to their affinities being with the Annelids instead of with the Mollusca, as generally believed. The following is his concise summary :—"Ancient Chaetopod worms culminated in two parallel lines—on the one hand in the Brachiopodæ, and on the other in the fixed and highly cephalized Chaetopods. The divergence of the Brachiopodæ, having been attained in more ancient times, a few degraded features are yet retained, whose relationships we find in the lower Vermes ; while from their later divergence the fixed and cephalized Annelids are more closely allied to present free Chaetopods." The author lays stress on the certainly soft and uncalcified condition of the earliest forms of life causing great imperfection in the earliest geological record.

IN the death of Mr. William S. Sullivant, which is recorded in the scientific columns of *Harper's Weekly*, and which took place at Columbus, Ohio, on April 30 last, the United States has lost one of its most accomplished botanists, especially in the department of the mosses, in which he was the recognised head for many years. From a biographical notice published by Professor Gray in the *American Journal of Science*, we learn that Mr. Sullivant was born in 1803, near Columbus, in the vicinity of which place he resided the greater part of his life. His first publication appeared under the title of *Musci Alleghanienses*, a work on the mosses and liverworts of the Alleghany Mountains, illustrated by prepared specimens of the plants themselves. This was shortly after 1843, and a few years later a work on the same subject was published in successive numbers as a memoir of the American Academy. The section of Mosses and Hepaticæ in Prof. Gray's *Botany of the Northern United States* was prepared by Mr. Sullivant, and credited to his pen. A separate edition was subsequently published by the author. A work on the mosses of Cuba was prepared by him, illustrated by specimens collected by Mr. Charles Wright. He also published, in 1859, the account of the mosses collected by the Wilkes expedition. The most important of Mr. Sullivant's publications, however, consists of his *Icones Muscorum*, being "figures and descriptions of most of those mosses peculiar to Eastern North America which have not been heretofore figured"—this forming an imperial octavo volume with 129 copper-plates. It is stated by Prof. Gray that a second or supplementary volume of *Icones* was in preparation by Mr. Sullivant, and nearly completed at the time of his death.

THE additions to the Zoological Society's Gardens during the past week include two Mouflons (*Ovis musimon*) from Sardinia, presented by Mr. H. E. Holloway ; two Barbel (*Barbus vulgaris*) and a Bream (*Abramis brama*) from British seas, presented by Mr. E. S. Wilson ; two Sacred Ibises (*Geronticus æthiopicus*) from Gough's Island ; a Black-handed Spider Monkey (*Ateles melanochir*) from Central America, purchased ; five Horned Lizards (*Phrynosoma cornutum*) from California, deposited.

SPÖRER'S OBSERVATIONS ON THE SUN*

THE author gives chiefly the results of his spectrum observations, and simultaneous spot observations, recorded in the Transactions of the Berlin Academy of Sciences for November 1871, and May 1872. To the two earlier instances of striking changes observed in the protuberances, there is added an interesting observation of August 8, 1872. It was estimated that the prolongation of the upper part of the protuberance had a velocity of forty-two kilometres per second, parallel to the sun's surface. In the case of many protuberances, it will be readily allowed that they are not only subject to cyclones, but also owe their origin to them. Protuberances of similar form, observed on several successive days, in the same heliographic latitude, Spörer has accounted for, by the supposition of volcanic eruptions, owing to the smaller rate of linear rotation of the deeper strata ; if, however, we regard these protuberances as the results of cyclones, the explanation of the changes of position would rest upon the impelling power of the storms, and their tendency to create new forms ; and the velocity of the advancing cyclone would, in several instances, average 1·4 kilometre.

Spörer, in this work, adheres to his division of protuberances into two classes. Secchi, in his work on the Sun, has distinguished four classes of protuberances, but afterwards accepted Spörer's twofold division. Both observers are at one in this, that the protuberances, which Spörer has named "flame" and Secchi "ray" protuberances, give different spectral lines, and stand in intimate connection with the spots. But with regard to the proper hydrogen protuberances, Secchi says they are not in the condition to give rise to a spot, against which Spörer adduces examples of their influence in neighbouring spot formation, especially prominent in the intervals between considerable protuberances of hydrogen.

The observation of the protuberance, which Secchi also noticed, on July 7, 1872, and which gave a well-marked image with the line 6543, is particularly described, and drawings are appended.

With regard to observations of spots, interesting comparisons are given, showing the difference between the two hemispheres in respect to the frequency of spots, and the mean heliographic latitudes. In this connection, Carrington's observations, from November 1853 to the beginning of 1861, are gone into, so that the comparisons embrace a period extending from November 1853 to the end of 1871. With regard to frequency of spots, it appears that the southern hemisphere exceeds the northern both in maximum and minimum. The curves also show distinctly the rapid passage from minimum to maximum, and the slow decrease after the maximum.

The mean heliographic latitudes are obtained through assigning to each group of spots, a factor of value (*Werthfactor*). The union of five-rotation periods gave a point of the curve for the northern as well as for the southern hemispheres. Carrington had obtained from his observations the striking result, that the spots at the time of the minimum approach the equator, thereafter veered off to higher latitudes, and that then the more numerously spotted zones gradually approached the equator. Spörer, by his observations since 1861, has confirmed this result.

* Translated from a review in *Der Naturforscher*, No. 29, of Beobachthungen der Sonne, von. Prof. Dr. Spörer, Abhandlung zum Programm des Gymnasiums. Separat-Abdruck. Anklam. Verlag und Druck von Richard Poettcke : 1873.

THE AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

THE meeting of the American Association for the Advancement of Science was held this year at Portland, in the State of Maine, during the fourth week of August; there was a large attendance of well-known scientific celebrities and members. The following account, for which we are indebted to the *New York Tribune*, will give an idea of some of the most important papers and discussions.

A discussion on the Darwinian hypothesis, which was started by Prof. Swallow, who is a vigorous opponent, was continued by Dr. Dawson, who began by stating with some fullness of detail the demands upon our credence made by the advocates of the evolution theory. Among other requirements of the theory, he said, it must provide an explanation of the origin of life. To accomplish this the experiments of Bastian were brought forward. Referring to these, he stated that no less an authority than Prof. Huxley, though an evolutionist, had denied their conclusive character and disputed the alleged results. We are expected to admit, in every department to which scientific inquiry relates, that in all things there has been a successive progress from the lower to the higher. Why should we make this admission? What proof is there of it? The recent discoveries of embryology, showing the likeness of early forms of the embryo to other animals of the same families, furnished to the advocates of evolution no real argument in its favour. They proved nothing. Admit if you will the close resemblance of similar bones and general physical structure in the ape and man, it is not the slightest evidence of identity. While it may be true that there is bone for bone in monkey and in man, still it remains that the bones of one are different from those of the other. The making of monkey and of man is explicable quite as readily, to say the least, on the theory of plan as on that of evolution. The history of the growth of an animal has been cited as the evidence of a development from a lower to a higher form. But what are the facts in the case? The egg grows into the animal, and that organism produces an egg again. This is revolution, not evolution.

We are told to accept as a postulate that mind too is a result of development; that the moral as well as the material being is simply a consequence of the evolving process. I do not grudge the naturalists who have adopted such theories the intellectual exercise which is involved, but I regret that much of their labour is wasted, and the results will be burnt when the fires of truth are applied to the chaff they are accumulating. This is not a question of physics that they are arguing, it is one of metaphysics, and it would be well for our children as well as growing scientists if they were taught more of mental and moral philosophy as a basis for such inquiry.

But I thank the students who are thus engaged for some good results of their exertions. They have thereby succeeded in reducing the superfluous numbers of species, and have obtained far better views in respect to classification. Good results will also flow from the profound embryological researches of the day. But I am sorry for the investigators, for their reputations are at stake, and they have chosen a mistaken path.

We are, however, approaching in our studies a correct theory. After its appearance in geological history, every species has a plastic tendency to spread to its utmost limits of form. Then ensues a period of decadence until it may become extinct. This has been set forth in some of my printed memoirs on the plants of the carboniferous series. I believe that a similar process is true of the human race. He referred to the skull of Mentone and its finally developed character—a grandly developed man cerebrally and bodily. The burial of his dead testified to his religious belief. The people of the Cromagno skull age were of a similarly elevated character. The only point of difference from men to-day was in the flattening of one of the leg-bones. This was perhaps a result of the habits of the tribe, running through forests in pursuit of game. It begins to be admitted that the man of Western Europe came in with the modern mammalia at the close of the glacial period. This was a period of decadence, and when the pliocene fauna were dying out and new forms were taking their places. The most ancient form of man is beyond the average standard of modern humanity. If the man of Cromagno or Mentone had been sent to Harvard, he would have been graduated with the full honours of an average American student.

Prof. Morse stated that Dr. Dawson and Prof. Swallow had both misquoted Prof. Huxley, who had said, in respect to the ancient skull referred to, that it might have held the brains of a thoughtless savage, or it might have contained those of a philosopher. Dr. Dawson had referred to only the differences in those remains from those of the man of to-day in respect to the flattened tibia. There were, however, several other characters of a similar nature which Dr. Dawson had not referred to, some of which had been discovered by Prof. Wyman, and had not yet been published. In the existing races of man the *foramen magnum* (the large opening at the base of the skull through which the brain communicates with the spinal cord) exhibited very little change of position in its relation to the rest of the skull, while with the higher primates (apes) this opening is very near the posterior portion of the skull. In eleven ancient skulls from the shell heaps of Tennessee, the *foramen magnum* in every case was nearly an inch further back than in those of present existing races. The powerful muscles on the sides of the head that move the jaws leave a distinct line at their upper points of attachment. These lines are called temporal ridges. In all present existing races a space occurs on the top of the skull, between these lines, of from three-and-a-half to four inches. In the apes these muscles meet in the median line which rises into a bony crest so characteristic of the gorilla. There was a remarkable skull discovered by Prof. Wyman in the lowest beds of the ancient shell heaps of Florida. This has the temporal ridges approaching each other within a half inch at the top of the skull. If the high development of the skull referred to by Mr. Dawson was such as he states, it only carries man further back. Similarly, in the light thrown upon the history of man by the wonderful discoveries in archæology, where we meet with traces of an ancient civilisation, with complicated language and manners, we can surely believe in savage hordes pre-existing from which this ancient civilisation has been evolved.

As to the early traces of man, we must fully appreciate the rare possibility of their occurrence. Wherever you dredge in the waters of the present day the traces of man are among the rarest discoveries. The Lake of Haarlem, upon whose waters naval battles have been fought, and on whose shores a dense population has existed, was drained, and on its bottom not the slightest traces of man's existence were found. Prof. Morse dredged repeatedly for years off the shores of Maine, and no trace of man was ever brought up, except a single spike. When we consider how abundant the material for such remains must be now compared with those furnished by the simple methods of life and the sparse population of earlier days, the indications of man's existence in geological eras must be of the rarest occurrence. In fact, in such rocks as the drift, only the rude stone implements could be preserved.

The evolution theory as compared with that of special creation presented similar features to the undulatory theory of light as compared with the emission theory. Newton's theory required a new modification with every discovery in optics, until, as a writer said at that time, the emission theory is a mob of hypotheses. The undulatory theory of Young not only explained all that was difficult to Newton, but gave physicists the power of prevision. So with evolution. It not only accounts for existing phenomena, from the modification of a flower or the spot on a butterfly's wing to the genesis of the solar system, but it has endowed naturalists with the gift of prophecy and enabled them to predict the intermediate forms afterwards discovered in the records of the rocks.

On Calvert's Supposed Relics of Man in the Miocene of the Dardanelles. By G. Washburn.—The author reports, in view of the facts to which the paper refers, as to the flints, the split bones, and the marks upon the fossil bone, that he believes that Mr. Calvert and Sir John Lubbock (who had never seen the specimens) are mistaken in the conclusions to which they have come, and that they have not been able to find any evidence whatever at the Dardanelles in reference to the antiquity of man.

The Rotation of the Planets as a Result of the Nebular Theory. By Prof. Benjamin Peirce.—Prof. Peirce's paper set forth an explanation of the actual rotation of the planets on the supposition of their being formed according to the nebular hypothesis, from rings thrown off from the rotating main body in the process of condensation. He instanced more particularly the planets Jupiter and Saturn. The inner portions of such a ring having a less velocity than the outer ones, axial rotation in the same direction as that of the primary would be determined in the breaking up and running together of the ring into a planetary body. He showed, by a mathematical analysis of the movements of the particles com-

posing the ring, that the velocity of the resulting rotation must be such as is actually observed in the case of the planets referred to, whose mass represents nine-tenths of the whole planetary system.

In Jupiter and Saturn, the velocity of a particle in the planet is very nearly the velocity of the planet itself. Then Jupiter and Saturn must have derived their material from the whole mass of the planetary system. The best theories of the earth make it of uniformly decreasing density from the surface to the centre. Suppose that after Jupiter were formed it were condensed, that might otherwise explain its velocity. He showed that, in the case of the planets, the velocity, had it been one-half what it actually was, would have resulted in their having no rotation. This theory was applied to the absence of rotation in the case of our satellite. He showed the probability that the original nebular ring from which the planets were formed may have been of twice the size of their present orbits. The nebular theory, to meet the requirements of the mere mathematician, would have placed all the planets at regular distances, and given them exactly similar motion. But not such was the method of nature.

In the discussion which followed he stated that we have never seen anything of Jupiter or Saturn but the clouds which cover them. He thought that those planets were yet at a white heat, and we simply saw the clouds that are raining down upon them. The present state of the satellites may be a result of their tides, and not the index of their original velocity. Jupiter and Saturn took so large a proportion of all the planet-forming material that the laws impressed upon them may serve best to tell the whole history of the solar system. There may be, however, a rotation of the inner mass of those planets of which we know nothing.

Geology of Southern New Brunswick. By Prof. T. Sterry Hunt.—The recent labours under the Geological Survey of Canada, by Messrs. Bailey Matthew and the author, were sketched. They show south and west of the coal basin various uncrystalline formations, all resting upon ancient crystalline rocks. These latter are by the author regarded as for the most part the equivalents of the Green Mountain and the White Mountain series, or what he calls Hurordan and Montalban. These are penetrated by granites, and associated in one part with Norian rocks, but the presence of Lamentran is somewhat doubtful. While the author recognises thus, at least, four distinct series of pre-Cambrian crystalline rocks in Eastern North America, he does not question the possible existence of yet other series in this region. The analogies offered by the more recent rocks of this region are very suggestive.

On the Possibility that the Sun, while mainly Gaseous, may have a Liquid Crust. By Prof. Charles A. Young.—There can be very little doubt that Secchi and others, who hold that the sun is mainly gaseous, are correct in this: the smallness of density cannot possibly be explained on any other supposition. At the same time the eruptional phenomena which are all the time occurring on the surface, almost compel the supposition that there is a crust of some kind which restrains the imprisoned gases, and through which they force their way in jets with great violence.

Prof. Young suggests that this crust may consist of a more or less continuous sheet of descending rain, not of water, of course, but of the materials whose vapours exist in the solar atmosphere, and whose condensation and combinations are supposed to furnish the solar heat. As this tremendous rain descends, the velocity of the falling drops would be retarded by the resistance of the denser gases underneath; the drops would coalesce until a continuous sheet would be formed; and these sheets would unite and form a sort of bottomless ocean resting upon the compressed vapours beneath, and pierced by innumerable ascendir jets and bubbles. It would have an approximately cons‘J .t depth in thickness, because it would re-evaporate at the b‘ ‘om nearly as rapidly as it would grow by the descending rains above, though probably the thickness of this sheet would continually increase at some slow rate, and its whole diameter diminish.

Prof. Young added an explanation of the narrow disc fringes seen at the moment of totality in a total eclipse, showing them to be optical interference effects caused by the sudden changes of the temperature of the air at the edge of the shadow. The twinkling of stars is analogous in many respects.

The Existence of Live Mammoths. By Prof. Feuchtwanger.—The discovery of the mammoths in Siberia in the deep gorges of the mountains near the Lena Viner, which was lately published as having been made by a scientific Russian convict, who five living animals, twelve feet in height and eighteen feet in length, with projecting tusks four feet long, excites some discussion in Europe. I think it worthy of inquiry whether the mammoth of the past tertiary period, discovered during this century in Siberia, near the same river, can have any relation to the convict's discovery. Thousands of these animals have been found buried in the ice, with their well-preserved skins, and thousands of tusks are brought to England to this day for the use of the turner. These are of nearly the same dimensions as those seen by the Russian. The convict has received an unconditional pardon, on the recommendation of scientific men who have investigated his statements and believe them to be true.

Prof. E. S. Morse, of Salem, Mass., read a paper on the subject of *Variations in Wave Lengths.* Prof. Morse first called attention to the interesting discoveries of Lockyer, Huggins, and others in accounting for the displacement of lines in the spectrum in observations of celestial objects. It is well known that when a star is approaching the observer the luminiferous waves emitted by it are crowded together, and on the contrary are separated when the star is receding.

Mr. Morse brought forward an instrument by which this phenomenon in the case of light may be easily and plainly illustrated before a large audience. The instrument consists of a tank filled with water and set on wheels. On the top of this is a compartment containing compressed air. From one end of the tank a pipe protrudes, which is moved up and down at a fixed rate by simple clockwork. When the cock is opened, allowing the water to escape from the pipe, the stream assumes a sinuous line, which may be shown, if brilliantly lighted, across a large audience hall. This undulatory stream, when the tank is at rest, illustrates a luminiferous wave from a stationary source. To exhibit the shortening or lengthening of the waves of light by the approach or recession of the luminiferous body, Mr. Morse simply moves the apparatus rapidly back and forth on the table. As the apparatus moves with the direction of the stream its undulations are crowded together, and the waves are consequently shortened. On the other hand, when the motion of the apparatus is in an opposite direction, the waves are proportionably lengthened. The advantage of this illustration is that it exhibits precisely what takes place in the luminiferous waves approaching or receding from the observer of celestial bodies, producing the displacement of spectrum lines.

Concerning Hyalonema. By Dr. Samuel Lockwood.—The recent deep-sea dredgings have done much toward clearing up the singularly anomalous history of the Japanese glass-rope sponge. Prof. Lockwood, however, thinks that, either from inappreciation or otherwise, the knowledge thus obtained has not been applied to the elucidation of certain mooted points connected with Hyalonema. With regard to the mistakes in representing Hyalonema "wrong end up," my opinion is that the error was led off by the Japanese themselves. The drawings by the native artists represented these curious objects as attached to the sea bottom by the sponge mass, thus making the fascicle to be erect and uppermost. Obtained by the net, or some such means, from the bottom at great depths, it is supposable that the fishermen at Enoserma were entirely ignorant of the matter. Their theory, however, as represented by the native artists, has wrongly represented the Hyalonema. These ropes attached to the sponge and sand are some distance from the main or upper portion encrusted with parasites. After removing portions of the encrusting case from the fascicle, he could not detect any structural evidence that Polython owed anything for food to the object which had gi· en it local support. It, however, "chums" with the sponge f a purpose of its own. Prof. Lockwood thinks that it draws ·ustenance from the fishing process of its radiating tentacles.

Both Polyps and sponge provide for themselves. In his view the zoöphyte is what we must call a compensal, and could not exist without that sort of support from Hyalonema which the oak affords the vine: and Hyalonema, too, is a compensal; for how long would it endure without the support of Polython? The stem, without this support, would not be able to hold itself erect. Other varieties are supported by stems consisting of sheaves of short spicules, bound together by bony cement. These have and need no supporting Polythoa. He combated the view that Hyalonema was sunk in the mud up to the neck, arguing that the polyps surrounding the stem could not so live; that it could not use its tentacles to obtain food, and that the position of the egg-cases of the deep-sea shark, the oldest egg being attached, and the most recent at the bottom, sustained this view. Some account was then given of the material structure of the encoating Polython. The essayist spoke of the deep-sea sharks off Setubol,

making that place their feeding-ground, because of the facility afforded them to secure these egg-cases by the abundance of the Hyalonemas there.

The Co-efficient of Safety in Navigation: an attempt to ascertain within what Limits a Ship can be located at Sea by Astronomical Observations. By Prof. Wm. A. Rogers.—This was an attempt to ascertain mathematically the average number of miles that a ship may be out of her reckoning. It was a paper of length, indicating long and careful research. It stated that in the case of British vessels there is a continual increase in the proportion of wrecks, as shown in the following :—

British vessels.	Wrecks.
Inc. 1858 over 1848......38 per cent.	Inc. 1862 over 1852......59 per cent.
Inc. 1868 over 1858......44 per cent.	Inc. 1867 over 1857......57 per cent.

For 1869 we have a decrease in the number of vessels of 4 per cent., and an increase in the number of wrecks of 21 per cent. The confidence in reckoning by instruments had increased the danger. He considered separately (1) wrecks by causes beyond control; (2) wrecks to obtain insurance; (3) wrecks by deviation of compass; (4) wrecks by errors of observation. He concluded that 70 per cent. of wrecks were from preventible causes. There are 3·3 times as many insured vessels wrecked as uninsured. The ratio of errors in chronometers wasillustrated in an elaborate series of tables showing that the navigator must expect from this source an error of 3·6 miles, must be on the look-out for one of 11·5, and must not be surprised at one of 21 miles, all on the supposition that he has an average chronometer. One serious source of error is varying temperature during a voyage. The conclusion was that the navigator who assumes that he can get the place of his ship certainly within five miles, or probably within fifteen, exhibits an over-confidence which may lead to his ruin.

There were other papers of interest, by Prof. Elliott, on International Coinage; by Prof. Wheildon, on the Arctic Regions; by Gen. Barnard, on the Relation of Internal Fluidity to the Precession of the Equinoxes; by Prof. Hilgard, on Transatlantic Longitudes, and on Meridional Arcs; by Col. Whittlesey, on Rivers in the Mississippi Valley; by Prof. Hunt, on Breaks in the American Palæozoic Series; by A. E. Dolbear, on a new method of measuring the velocity of light.

*MR. HARTNUP ON DETERMINING THE RATES OF CHRONOMETERS**

THE difficulty in predicting the rate of a chronometer for a voyage arises from the imperfect state of the instrument; and by a well-arranged and carefully conducted test, these imperfections may be so exhibited as to enable the mariner to avoid the danger which must frequently follow from the neglect of such precautions. The Greenwich mean time is now so easily obtained in most seaports, that there can be no difficulty in ascertaining the daily gain or loss of a chronometer, if the rate so found could be depended on. The communication of time to the port of Liverpool, by the firing of the gun which is placed on the Morpeth Dock Pier Head, has been so successful that the difference between the flash of the gun and 1 P.M. Greenwich mean time has not, on any occasion during the past year, been such as could lead to an error in a ship's longitude to the extent of the width of the Mersey opposite the point on which the gun is placed; and by observing the flash of the gun on two occasions at an interval of a few days, the rate of a chronometer may be obtained with sufficient accuracy for most practical purposes. The rate so obtained might, however, differ very much from the rate at sea, if the temperature in which the rate was obtained in port differed much from that to which the instrument was exposed on the voyage.

Imperfect thermal adjustment is a defect so well known, that during the past thirty years the attempts made to improve the quality of marine timekeepers have been mainly confined to the compensation balance. The ordinary balance does not perfectly compensate for the change in the elasticity of the balance-spring, caused by change of temperature, and various forms have been given to balances with the view of attaining greater perfection. Balances have, without doubt, been made to compensate for change of elasticity in the spring throughout long ranges of temperature, but there is evidently some objection to their general adoption for the merchant navy. It is possible that the thinness of the laminæ, and peculiarity in the construction of balances which are made with the view of removing the defect above named, may render them less permanent in their action, and more liable to injury in the hands of a less skilful mechanic than the original maker; but however this may be, the ordinary balance seems to be almost universally used in the merchant navy. This having been found to be the case, about four years ago arrangements were made at the New Observatory for the trial of chronometers in three definite temperatures with the view of showing the amount of change in their rates due to error of thermal adjustment, and more than one thousand marine timekeepers have now been tested in 55°, 70°, and 85° of Fahrenheit. From a careful examination of the records of these tests there appears to be a definite temperature peculiar to each chronometer in which the instrument goes faster than in any other temperature, and as the number of degrees above or below this temperature of maximum gaining rate increases the chronometer loses in a rapidly increasing ratio. If we assume this law of variation to be that the change of rate is directly as the square of the number of degrees from the maximum gaining rate, the rates calculated on that assumption are found sensibly to agree with those obtained from observation; therefore, if we have the rate from observation for each of three definite temperatures, as given in my last two Reports, we can find, by computation, the correction for error of thermal adjustment due to any other temperature. In order to do this it is necessary to find—

T . . the temperature in which the chronometer has its maximum gaining rate,

R . . the rate at the temperature T, and

C . . the factor, or constant number, which multiplied by the square of any given number of degrees from T shows the amount of loss for that number of degrees.

The following example shows the method of calculating C, T, and R from the observed rates in 55°, 70°, and 85°:—

Chronometer, No. 727.

$$\text{Rate in } 55^\circ = -\overset{\text{s}}{2{\cdot}92} \ldots r$$

$$r - r' = -1{\cdot}04 \ldots d$$

$$,, \quad 70 = -1{\cdot}88 \ldots r'$$

$$r' - r'' = +1{\cdot}25 \ldots d'$$

$$,, \quad 85 = -3{\cdot}13 \ldots r''$$

$$d - d' = -2{\cdot}29$$

$$d + d' = +0{\cdot}21$$

$$C = \frac{2(d - d')}{30^2} = \frac{-4{\cdot}58}{900} = -0{\cdot}00509$$

$$T - 70 = \frac{d + d'}{C \times 60} = \frac{+0{\cdot}21}{-0{\cdot}3054} = -0{\cdot}69$$

$$T = 70 - 0{\cdot}69 = 69{\cdot}31$$

$$R = r' - (T - 70)\frac{d + d'}{60} = -1{\cdot}88 + 0{\cdot}69 \times 0{\cdot}0035 = -1{\cdot}878$$

From the preceding Examples

	Mean Daily Rate in 55°	in 70°	in 85°	C.	T.	R.
No. 727	s −2·92	s −1·88	s −3·13	−0·00509	69·31	−1·88

Let N = any number of degrees from T, then the Rate at $T \pm N = R + C \times N^2$.

Required the Rate of No. 727 at 40°
Here $N = 29{\cdot}31$ and $N^2 = 859{\cdot}08$

Therefore the Rate at $40^\circ = -1{\cdot}88 + (-0{\cdot}00509 \times 859{\cdot}08) = -6{\cdot}25$.

The values of C and T remain the same for long periods; as a rule, they do not sensibly change so long as the adjustments are not altered, and the instrument remains in good condition; but R is more changeable, and should be redetermined on all favourable occasions. To find the change in R the rate must be first carefully found in some definite temperature. Suppose, for example, that at some subsequent time the rate of No. 727 was found to be −2·13, instead of −3·13, in 85°, then the rate at T would be −0·88 instead of −1·88; but it might not be convenient to obtain the rate in either of the temperatures in which the rates are given in the test, and then it may be found as follows:—Suppose the rate has been found to be −1·55 in 81·5, then the rate must be computed for 81·5, on the assumption that R has not changed, and the difference between the rate observed and the rate computed will be the correction to be applied to R.

The computation is as follows:—$81{\cdot}5 - 69{\cdot}3$ or $N = 12{\cdot}2$ and $12{\cdot}2^2 = 148{\cdot}84$.

* Extracted from the Report of the Astronomer to the Marine Committee, Mersey Docks and Harbour Board, for the year 1872.

Therefore, the rate at 81·5 = − 1.88 + (− 0·00509 × 148·84 = − 2·64.

Observed rate in 81·5 = − 1·55. Computed rate in 81·5 = − 2·64. The losing rate at T must therefore be diminished by 1·09, making the newly found R = − 0·79 instead of − 1·88.

For any chronometer which has been allowed to remain at the Observatory for a period of five weeks the certificate of test issued with the instrument contains the necessary data for calculating the correction due to imperfect thermal adjustment.

THE WHITWORTH SCHOLARSHIPS

THE following Memorandum on the Whitworth Scholarships, prepared by Sir Joseph Whitworth, has been approved by the Lords of the Committee of Council on Education, South Kensington :—

1. The experience of the past competitions for my scholarships has proved to me the necessity of establishing rules which shall insure that the holders of scholarships shall devote themselves to the studies and practice necessary for mechanical engineering during the tenure of the scholarships.

2. To effect this I propose to the Lords of the Committee of Council on Education that as soon as possible, *i.e.* in the competition of 1875, every candidate for a scholarship should produce a certificate that he has worked in a mechanical engineer's shop, or in the drawing office of a mechanical engineer's shop, for two years consecutively. In 1874 six months' consecutive work only in the engineer's shop will be required. The candidate must be under 22 years of age.

3. The candidate for the scholarship will be examined in the appointed sciences; in smith's work, turning, filing, and fitting, pattern making and moulding, as already established, and the same marks will be awarded as at present.

4. In 1875 and the following years each holder of a scholarship appointed under these new rules will be required to produce satisfactory evidence at the termination of every year that he has made proper advances in the sciences and practice of mechanical engineering by coming up for an examination similar to that which is prescribed for the competition both in theory and practice.

5. The scholarships may be held for three years, but may be withdrawn at the end of each year if the scholar has not made satisfactory progress.

6. The number of scholarships in the competition of 1874 will be reduced from ten to six. Each scholarship will be of a fixed annual value of 100*l.*, together with an additional annual sum determined by the results of the progress made in the preceding year.

7. At the end of each year's tenure of the scholarship, the scholars appointed under these new rules will, as before stated, be examined in theory and in practice in the same manner as in the competition for the scholarships. On the results of this examination the following payments, in addition to the 100*l.* before mentioned, will be made among each year's set or batch of scholars :—To the scholar who does best in the examination, 100*l.*; to the second, 60*l.*; to the third, 50*l.*; to the fourth, 40*l.*; to the fifth, 30*l.*; and to the sixth, 20*l.*; provided that each scholar has made such a progress as is satisfactory to the Department of Science and Art, which will determine if the sum named, or any other sum, shall be awarded.

8. At the expiration of the three years' tenure of the scholarships under these new regulations a further sum of 300*l.* will be awarded in sums of 200*l.* and 100*l.* to the two scholars of each year's set or batch who have done best during their tenure of scholarship.

In this way it will be possible for the best of the scholars at the end of his period of tenure of the scholarship to have obtained 800*l.*, and the others in proportion.

9. The prizes under paragraph 7 will be awarded according to the total number of marks obtained by the students in practice and theory in the examination at the end of the year. The prizes under paragraph 8 will be awarded by adding together the marks obtained by the students at the end of each of the three years.

SCIENTIFIC SERIALS

THE current number of the *Zoologist* commences with a notice by the editor, of Mr. Lloyd's "Official Handbook to the Crystal Palace Aquarium." In an interesting historical sketch of the growth of aquaria, he divides its development during the last forty years into three eras, the earliest being the instructive, the second the poetic and fashionable, and the present the commercial. The early development of the aquarium is then entered into, the work done by Bowerbank, Daubeny, and Warington being fully described. This is followed by a review of Mr. T. J. Moggridge's work on Harvesting Ants and Trapdoor Spiders, in which the author, from a careful and painstaking series of excellent observations on the habits of ants, which are described in detail, shows that the old idea that these insects do accumulate seeds in store-houses for winter consumption is correct, contrary to the assertions of Kirby, Latreille, and other high authorities. What is very peculiar is that these seeds scarcely ever show any tendency to germinate, though under apparently very favourable circumstances.—Mr. Cornish notes the occurrence of the following fish at Penzance :—The Black Fish (*Centrolophus pompilus*), the Solenette (*Monochirus linguatulus*), the Braize (*Pagrus vulgaris*), Bloch's Gurnard (*Trigla blochii*), and the Torpedo (*Raia torpedo*).—Mr. F. H. Balkwill, in reply to a critical note which appeared in this journal (NATURE, July 24, p. 252) on a paper by him in the *Zoologist* for July last, objects to his remarks being thrown into the general form; the fact that the forms and arrangements of teeth in vertebrates is practically infinite, being assumed by him. But that such is very far from being the case will be agreed to by all zoologists; the types and arrangements of teeth being extremely few in comparison to what they might be. The argument does not require, as Mr. Balkwill thinks, the proof of the statement that the teeth of the wombat, dog, &c., should be of low type and simple development, which they are not; and he may be assured that all "genuine Darwinists" are of opinion that when two not distant types of animal life are in a position to occupy new and separate regions, the fact that their food can only be obtained from two sources, namely, animal and vegetable tissues, invariably leads to their divergence in two directions only, that is, towards a carnivorous and a herbivorous conformation. Therefore the non-placental type, on occupying Australasia, as well as the placentalia in the rest of the world, have differentiated into flesh-eaters and vegetable-eaters, each having developed, by natural selection, organs suitable for procuring their accustomed diet. It is not therefore to be wondered at that these organs should present many points of similarity in the two main divisions of the Mammalia.

BARON VON MALTZAN gives in the second number of the *Zeitschrift für Ethnologie* for 1873, an account of his travels in Arabia, and points out the various causes which have opposed the advance of our knowledge of its interior. Amongst these religion has acted as the most powerful obstacle, the exclusiveness of the Islam faith having, in fact, so effectually closed the country to modern research, that there are still many spots of which nothing is known beyond what Ptolemy was able to tell us. Baron von Maltzan selected the most southern extremity of the peninsula, which is as yet a *tabula rasa* on our maps, for the scene of his explorations. He draws attention to the artistic skill exhibited by these people in statuary and carving, before they fell under the rule of their Mahomedan conquerors from Central Arabia, when all their earlier civilisation was rudely checked and their language superseded, while they were then also first driven to adopt a monadic mode of life. In spite, however, of amalgamation with central Arabian elements, the population of South Arabia still admits of division into two distinct peoples, the Sabäer and the Himyarites, the former of whom have light yellow skins, while the latter, whose name he derives from *Hamr*, red, are so dark-skinned as to be genrally classed amongst the black races. Baron Maltzan observed a curious physical character in the family of the Himyarite rulers of the Fodli, or Ozmani-State, many of whom, both males and females, had six fingers and six toes on both hands and feet. This peculiarity is looked upon by the people at large as a special mark of blue blood, and prized accordingly by the possessors. It would seem that the practice of forming consanguineous marriages, which prevails in the Fodli, as in other ruling houses, may of itself explain, as a mere case of hereditary recurrence, the appearance of this physiological character in numerous and remote members of the family. The author concludes his paper with an appeal to men of Science to turn their attention to a region which is at once so little known and so rich in materials of interest for physiologists, ethnologists, and geographers.—Herr von Martens, in a critique on Prof. Strobel's paper on the appearance of *Unio* shells in the pile-dwellings of Upper Italy

and in the Paraderos Patagonians, draws attention to the diversity of opinion to which the occurrence of this bivalve has given rise, Dr. Boni deducing from it the theory that the Emilian Terremare are the sites of human habitations on artificially constructed water basins, whilst Dr. Coppi regards them as the remains of sacrificial or other slaughter places. Dr. von Martens has ascertained by personal observation that the Paraderos of Patagonia resemble in very many respects the Danish Kjökkenmöddings. It is worthy of note in reference to this subject that shells of the Adriatic form (*Aporrhais pes pelicani* and *Venus verrucosa*) occur in the Moravian pile-dwellings near Olmütz, while Mediterranean shells (*Cypræa pyram* and *hirida*) have been found on the Dordogne. These facts, which afford incontrovertible evidence of the extension of commerce in prehistoric ages, are corroborated by the appearance of Red Sea if not Indian Ocean forms of shells, as *Eburna spirata* in a Mariera at Reggio, and of *Cypræa pantherina*, in the Allemannic tumuli of Würtemberg. It has been suggested by Dr. E. Friedel that the *Unio pictorum* L., and the *Alasmodonta compressa*, which are so abundant in Italian Lacustrine deposits, may be connected with the presence of domestic swine, as these bivalves constitute in the present day a very important element in the food of these animals in the poorer districts of the Oder and the Brandenburg Mark.—In conclusion we would draw attention to a curious paper read by Herr von Meyer before the Anthropological Society of Berlin on the origin of "Right and Left," and the causes which have led mankind to give the preference to one over the other, in using the hands and feet. The superior estimation of right over left is shown alike in the most ancient forms of Egyptian sculpture, in Jewish ordinances, in Hellenic poetry, and in language generally, whether of Turanian, Scythic, or Aryan origin. In these tongues the right hand is synonymous with what is good, straight, and right, while the left is identical with what is awkward, evil and abnormal. The author attempted to explain the universally diffused preference for the right hand on the ground of instinctive religious veneration in primæval man, who raised the right hand in adoration as he traced the course of the sun from its rising to its setting, while Prof. Virchow was inclined to refer it to a primary physical principle of the human organisation. The subject gave rise to an animated discussion in the Society, and led to the consideration of several questions of interest to the student of ethnology.

Sitzungsberichte der naturwissenschaftlichen Gesellschaft Isis in Dresden. Oct.—Dec. 1872.—The principal paper in this number is one by M. Ackermann, giving a comprehensive account of recent deep-sea researches.—Dr. Hoffmann furnishes a critique of Zöllner's work on comets; and among the shorter notices will be found information on Phylloxera, the physical features, climate, and products of Venezuela, silkworm-cultivation, the Zoological Garden at Dresden, and other topics.—The succeeding number (Jan.—Mar. 1873) consists, in great part, of zoological lists.—M. Rostock enumerating the Neuroptera of Saxony, and Dr. Köhler the Gasteropoda and Conchifera of Schneeberg.—In the botanical section, M. Wilhelmi gives a list of plants found on the Murray river in Australia.—M. von Kiesenwetter communicates a paper on the history of zoology to the time of Linnæus, being chiefly an abstract of Carus's work on the subject in a voluminous "History of the Science in Germany," now in course of publication.

THE *American Journal of Science and Arts*, Sept. 1873.—In a fifth paper on some results of the earth's contraction from cooling, Prof. Dana treats of the formation of continental plateaux and oceanic depressions, thus concluding the reconsideration of the views he brought out in 1847. Besides the admission of a solid nucleus and the present partial union of the crust to the nucleus, these views have been modified in some points connected with mountain-making and metamorphism, in accordance with ideas developed by Le Conte and Mallet, and the results of personal study. The author gives a valuable summary of his progress.—Prof. O. Rood has a paper on the residual or secondary spectra which Brewster studied, and which are obtained when white light is passed through two prisms of different substances, so arranged as to compensate each other for colour. The Professor has obtained a large dispersion in such spectra by using as one of the constituents the spectrum furnished by oil of cassia, bisulphide of carbon, or flint glass, the other being the *normal spectrum* from a diffraction grating. Some curious experiments with these are described.—A paper on the explorations last year, by the Snake River Division of the U.S. Geological Survey of the Territories, is furnished by Prof. Bradley; and another geological paper, by Mr. Washburn, treats of the Bosphorus region. There are also notes on the Corundum of North Carolina, Georgia, and Montana; on minerals found at the Tidley Foster Iron Mines, New York; on an apparatus for rapid filtrations; and on the discovery of a new double star β Delphini.

SOCIETIES AND ACADEMIES

PARIS

Academy of Sciences, Sept. 1.—M. Bertrand in the chair.—The following papers were read:—On the Aurora Borealis, by M. Faye. The author's paper related to Donati's late memoir on the same subject, in which he suggests that the passage of electro-magnetic currents from the sun to the planets is the cause of this phenomenon. M. Faye, on the other hand, deprecated the introduction of such a theory, and suggested that the effect of gravity as an agent in producing these effects may at least be probable. He suggested that motions such as are observed in the tails of comets might occur in the upper regions of our atmosphere, *i.e.* that excessively attenuated air might be constantly rushing from the side of the earth turned towards the sun to that turned from it, and that this motion might cause incandescence of the air, visible at the poles as auroræ.—On the Carpellary Theory as regards the *Amygdalaceæ*, by M. A. Trécul.—Gnomonic projection, &c., of a portion of the Sahara, by M. A. Pomel.—Study of the metallic veins of Cornwall; structure of the rich veins, and their relation to the stratigraphical arrangement of the country, by M. Moissenet.—On the Siemens coil, by M. A. Pellerin.—Observations of Planet 133 and of Borrelly's comet, by M. Stephan.—On the changes of form of Comet IV., 1873, and on its spectrum, by MM. G. Rayet and André. The comet has developed a tail and become brighter; it has no nucleus. Its spectrum at first consisted of three bands, one between D and E, another very close to b, and a third beyond F. After the tail had developed the same bands appeared, but they were larger and brighter and accompanied by a faint continuous spectrum.—On the form of the Martial seas as compared with the terrestrial oceans, by M. Stan. Meunier. The author considers that the long narrow straits on Mars are an additional proof of its greater age as compared with the earth. Taking the soundings of the Atlantic, he observed that if its level were reduced 4,000 metres (by absorption), it would then present a similar aspect to the Martial seas.

SCIENTIFIC WORTHIES

I.—Faraday

Michael Faraday, born September 22, 1791, *died August* 25, 1867.

WITH this number of NATURE we present to our subscribers the first of what we hope will be a long series of Portraits of Eminent Men of Science.

This first portrait is one of Faraday, engraved on steel, by Jeens, from a photograph by Watkins. Those who had the happiness of knowing Faraday best will best appreciate the artist's skill—he has indeed surpassed himself, for the engraving is more life-like than the photograph. We could ill spare such a memorial of such a man, one in which all the beautiful simplicity of his life beams upon us. There is no posturing here!

There is no need that we should accompany the portrait with a memoir of Faraday. Bence Jones, Tyndall, and Gladstone have already lovingly told the story of the grand and simple life which has shed and will long continue to shed such lustre on English Science, and their books have carried the story home to millions; nor is there any need that we should state why we have chosen to commence our series with Faraday; everybody will acknowledge the justice of our choice.

But there is great need just now that some of the lessons to be learnt from Faraday's life should be insisted upon, and we regard it as a fortunate circumstance that we have thus the opportunity of insisting upon them while our Scientific Congress is in session, and before the echoes of the Address of the President of the British Association for the Advancement of Science have died away.

In the first place, then, we regard Faraday at once as the most useful and the most noble type of a scientific man. The nation is bigger and stronger in that Faraday has lived, and the nation would be bigger and stronger still were there more Faradays among us now. Prof. Williamson, in his admirable address, acknowledges that the present time is "momentous." In truth the question of the present condition of Science and the ways of improving it, is occupying men's minds more than it has ever done before; and it is now conceded on all sides that this is a national question, and not only so, but one of fundamental importance. Now what is the present condition of English Science? It is simply this, that while the numbers of our professors and their emoluments are increasing, while the number of students is increasing, while practical instruction is being introduced and text-books multiplied, while the number and calibre of popular lecturers and popular writers in Science is increasing, original research, the fountain-head of a nation's wealth, is decreasing.

Now a scientific man is useful as such to a nation according to the amount of new knowledge with which he endows that nation. This is the test which the nation, as a whole, applies, and Faraday's national reputation rests on it. Let the nation know then that the real difficulty at present is this; we want more Faradays; in other words more men working at new knowledge.

It is refreshing to see this want so clearly stated in the Presidential Address:

"The first thing wanted for the work of advancing science is a supply of well-qualified workers. The second thing is to place and keep them under the conditions most favourable to their efficient activity. The most suitable men must be found while still young, and trained to the work. Now I know only one really effectual way of finding the youths who are best endowed by nature for the purpose; and that is to systematise and develop the natural conditions which accidentally concur in particular cases, and enable youths to rise from the crowd.

"Investigators, once found, ought to be placed in the circumstances most favourable to their efficient activity.

"The first and most fundamental condition for this is, that their desire for the acquisition of knowledge be kept alive and fostered. They must not merely retain the hold which they have acquired on the general body of their science; they ought to strengthen and extend that hold, by acquiring a more complete and accurate knowledge of its doctrines and methods; in a word, they ought to be more thorough students than during their state of preliminary training.

"They must be able to live by their work, without diverting any of their energies to other pursuits; and they must feel security against want, in the event of illness or in their old age.

"They must be supplied with intelligent and trained assistants to aid in the conduct of their researches, and whatever buildings, apparatus, and materials may be required for conducting those researches effectively.

"The desired system must therefore provide arrangements favourable to the maintenance and development of the true student-spirit in investigators, while providing them with permanent means of subsistence, sufficient to enable them to feel secure and tranquil in working at science alone, yet not sufficient to neutralise their motives for exertion; and at the same time it must give them all external aids, in proportion to their wants and powers of making good use of them."

Whether the scheme proposed by Dr. Williamson to bring such a state of things about will have the full success he anticipates is a matter of second-rate importance; what is of importance is, that the need of some scheme is now fully recognised.

So far the remarks we have made have been suggested by Faraday's usefulness. It is to be hoped that the nobleness of his simple, undramatic life, will live as long in men's memories as the discoveries which have immortalised his name. Here was no hunger after popular applause, no jealousy of other men's work, no swerving from the well-loved, self-imposed task of "working, finishing, publishing."

"The simplicity of his heart, his candour, his ardent love of the truth, his fellow-interest in all the successes, and ingenuous admiration of all the discoveries of others, his natural modesty in regard to what he himself discovered, his noble soul—independent and bold—all these combined, gave an incomparable charm to the features of the illustrious physicist."

Such was his portrait as sketched by Dumas, a man cast in the same mould. All will recognise its truth. Can men of science find a nobler exemplar on which to fashion their own life? Nay, if it were more widely followed than it is, should we not hear less of men falling away from the "brilliant promise" of their youth, tempted by "fees," or the "applications of Science," or the advantages attendant upon a popular exposition of other men's work? Should

we not hear a little less frequently than we do that research is a sham, and that all attempts to aid it savour of jobbery?

Lastly we may consider Faraday's place in the general history of Science; this is far from easy. Our minds are still too much occupied with the memory of the outward form and expression of his scientific work to be able to compare him aright with the other great men among whom we shall have to place him.

Every great man of the first rank is unique. Each has his own office and his own place in the historic procession of the sages. That office did not exist even in the imagination, till he came to fill it, and none can succeed to his place when he has passed away. Others may gain distinction by adapting the exposition of science to the varying language of each generation of students, but their true function is not so much didactic as pædagogic—not to teach the use of phrases which enable us to persuade ourselves that we understand a science, but to bring the student into living contact with the two main sources of mental growth, the fathers of the sciences, for whose personal influence over the opening mind there is no substitute, and the material things to which their labours first gave a meaning.

Faraday is, and must always remain, the father of that enlarged science of electro-magnetism which takes in at one view, all the phenomena which former inquirers had studied separately, besides those which Faraday himself discovered by following the guidance of those convictions, which he had already obtained, of the unity of the whole science.

Before him came the discovery of most of the fundamental phenomena, the electric and magnetic attractions and repulsions, the electric current and its effects. Then came Cavendish, Coulomb, and Poisson, who by following the path pointed out by Newton, and making the forces which act between bodies the principal object of their study, founded the mathematical theories of electric and magnetic forces. Then Örsted discovered the cardinal fact of electro-magnetic force, and Ampère investigated the mathematical laws of the mechanical action between electric currents.

Thus the field of electro-magnetic Science was already very large when Faraday first entered upon his public career. It was so large that to take in at one view all its departments required a stretch of thought for which a special preparation was necessary. Accordingly, we find Faraday endeavouring in the first place to obtain, from each of the known sources of electric action, all the phenomena which any one of them was able to exhibit. Having thus established the unity of nature of all electric manifestations, his next aim was to form a conception of electrification, or electric action, which would embrace them all. For this purpose it was necessary that he should begin by getting rid of those parasitical ideas, which are so apt to cling to every scientific term, and to invest it with a luxuriant crop of connotative meanings flourishing at the expense of the meaning which the word was intended to denote. He therefore endeavoured to strip all such terms as "electric fluid," "current," and "attraction" of every meaning except that which is warranted by the phenomena themselves, and to invent new terms, such as "electrolysis," "electrode," "dielectric," which suggest no other meaning than that assigned to them by their definitions.

He thus undertook no less a task than the investigation of the facts, the ideas, and the scientific terms of electromagnetism, and the result was the remodelling of the whole according to an entirely new method.

That old and popular phrase, "electric fluid," which is now, we trust, banished for ever into the region of newspaper paragraphs, had done what it could to keep men's minds fixed upon those particular parts of bodies where the "fluid" was supposed to exist.

Faraday, on the other hand, by inventing the word "dielectric," has encouraged us to examine all that is going on in the air or other medium between the electrified bodies.

It is needless to multiply instances of this kind. The terms, field of force, lines of force, induction, &c., are sufficient to recall them. They all illustrate the general principles of the growth of science, in the particular form of which Faraday is the exponent.

We have, first, the careful observation of selected phenomena, then the examination of the received ideas, and the formation, when necessary, of new ideas; and, lastly, the invention of scientific terms adapted for the discussion of the phenomena in the light of the new ideas.

The high place which we assign to Faraday in electromagnetic science may appear to some inconsistent with the fact that electromagnetic science is an exact science, and that in some of its branches it had already assumed a mathematical form before the time of Faraday, whereas Faraday was not a professed mathematician, and in his writings we find none of those integrations of differential equations which are supposed to be of the very essence of an exact science. Open Poisson and Ampère, who went before him, or Weber and Neumann, who came after him, and you will find their pages full of symbols, not one of which Faraday would have understood. It is admitted that Faraday made some great discoveries, but if we put these aside, how can we rank his scientific method so high without disparaging the mathematics of these eminent men?

It is true that no one can essentially cultivate any exact science without understanding the mathematics of that science. But we are not to suppose that the calculations and equations which mathematicians find so useful constitute the whole of mathematics. The calculus is but a part of mathematics.

The geometry of position is an example of a mathematical science established without the aid of a single calculation. Now Faraday's lines of force occupy the same position in electromagnetic science that pencils of lines do in the geometry of position. They furnish a method of building up an exact mental image of the thing we are reasoning about. The way in which Faraday made use of his idea of lines of force in co-ordinating the phenomena of magneto-electric induction* shows him to have been in reality a mathematician of a very high order

* To estimate the *intensity* of Faraday's scientific power, we cannot do better than read the first and second series of his "Researches," and compare them, first, with the statements in Bence Jones's "Life of Faraday," which tells us the tales of the first discovery of the facts, and of the final publication of the results, and second, with the whole course of electromagnetic science since, which has added no new idea to those set forth, but has only verified the truth and scientific value of every one of them.

—one from whom the mathematicians of the future may derive valuable and fertile methods.

For the advance of the exact sciences depends upon the discovery and development of appropriate and exact ideas, by means of which we may form a mental representation of the facts, sufficiently general, on the one hand, to stand for any particular case, and sufficiently exact, on the other, to warrant the deductions we may draw from them by the application of mathematical reasoning.

From the straight line of Euclid to the lines of force of Faraday this has been the character of the ideas by which science has been advanced, and by the free use of dynamical as well as geometrical ideas we may hope for a further advance. The use of mathematical calculations is to compare the results of the application of these ideas with our measurements of the quantities concerned in our experiments. Electrical science is now in the stage in which such measurements and calculations are of the greatest importance.

We are probably ignorant even of the name of the science which will be developed out of the materials we are now collecting, when the great philosopher next after Faraday makes his appearance.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

Tyndall and Tait

I HAVE hitherto refrained from intruding upon your space with reference to this deplorable Forbes' controversy, but now that the occasion has come when a brief deliverance on my part seems called for, I trust to your courtesy, if not to your justice, to allow me room for it.

In the first place I would ask permission to inform such of your readers as may feel an interest in the subject, that if they wish to form a correct opinion of the tone and logic of my rejoinder to Principal Forbes and his biographers, they will consult the rejoinder itself, as published by Longmans, and not the extracts and inferences of Professor Tait.

They will thus learn, among other things, that what Professor Tait calls "plausible," is simply unanswerable.

With regard to the taking up of the various points in Principal Forbes's reply, item by item, that may be done some day should I deem it a worthy occupation. In my rejoinder I converged attention on the two points which Principal Forbes himself considered the really serious ones, and having broken the neck of the argument in both these cases I cared little about prolonging the controversy. Nevertheless if circumstances show it to be necessary it may be prolonged.

Professor Tait invariably writes on the hypothesis that what is not contradicted cannot be contradicted, and must therefore be accepted as true—a natural, if not inevitable, assumption on his part. For example, Forbes's argument regarding the crevasses of Rendu was left unanswered by me, hence the conclusion that it was unanswerable. That argument, however, is now in shreds, as it might have been, had I so willed, any time during the last dozen years. Again, Principal Forbes makes an assertion regarding his tutelage of Agassiz; the assertion is left uncontradicted; it must therefore be accepted as true, and I am unjust because I do not so accept it. Thirteen years ago, however, I was in possession of a diametrically opposite assertion from M. Agassiz. Quite as distinctly, though not so specifically, he writes thus within the present year. "When Forbes came to visit me upon the glacier of the Aar, he knew not only everything that I had done, but also my plans for the future. When he left he positively declined to express any opinion concerning glacier phenomena, under the plea that he only came to gratify his curiosity, and had no intention of following up the subject, as he had no desire to be involved in the controversy then raging regarding the former extension of glaciers.* When he showed his hand I did not enter into a protracted discussion, but simply made a statement of facts and let the matter rest. . . . . When I look," adds M. Agassiz, "on the whole transaction it seems incredible. There is in it no vestige either of the gentleman or the honest investigator."

With statements of this character confronting the assertions of Principal Forbes, the proper course for me was to ignore assertions on both sides, and to confine myself to demonstrable facts. This I accordingly did.

With regard to Mr. Tait's criticism of my "popular" writings it has, of course, nothing to do with his defence of Forbes, but is the product of mere ignoble spite. He asks me to reply to him not according to the letter, but according to the spirit of his attack. If I might use the expression I would say, "God forbid!" for how could I do so without lowering myself to some extent to his level. The antecedents of Mr. Tait with reference to me are pretty well known. When I sought to raise from the dust a meritorious man whose name is now a household word in science, who has been elected by acclamation a member of the French Academy, and who has received the crowning honour of the Royal Society—when I sought to place Dr. Mayer in the position which he now holds, and from which no detraction can remove him, it was Mr. Tait who, in *Good Words*, charged me with misleading the public; who followed up his attack in the "Philosophical Magazine," and who when publicly hoisted by his own petard, retired to void his venom against me in the anonymous pages of the "North British Review." It is this man whose blunders and whose injustice have been so often reduced to nakedness, without ever once showing that he possessed the manhood to acknowledge a committed wrong, who now puts himself forward as the corrector of my errors and the definer of my scientific position. That position is happily not dependent upon him, and his opinion regarding it, is to me, as it will be to most others, a trifle light as air. But graver considerations than mere personal ones here arise. Might I venture, Mr. Editor, to express a doubt as to the wisdom of permitting discussions of this kind to appear in your invaluable journal. Having opened your columns to attack you are, of course, in duty bound to open them to reply, but if I might venture a suggestion, you would wisely use your undoubted editorial rights, and consult the interests of science, by putting a stop to proceedings which dishonour it. An illustrious person writes to me thus:—"I have just read Professor Tait's letters in NATURE, and feel a recurrence of that pain which similar communications once inflicted on myself—pain felt, not on my own account, for I knew that the attacks would no more sully me in the opinion of those whom I loved and respected, than they did in my own opinion; but pain for the wounded honour of science and the outraged dignity of scientific controversy."

JOHN TYNDALL

Athenæum Club, Sept. 16

[We deeply sympathise with Professor Tyndall's remarks on the injury done to scientific controversy by the introduction into it of personalities, and we should have made his own letter square with his canon if his reference to our duty in this matter, and his insinuation of injustice did not take the matter out of our hands. Prof. Tyndall forgets (1) that Prof. Tait's letter is an answer to a pamphlet by Dr. Tyndall, and that space was asked for it as such; and not an *attack* in the sense in which Prof. Tyndall uses the word; (2), that if the Editor were to assume the power and responsibility that Prof. Tyndall suggests, NATURE might easily fall from the position of absolute justice and impartiality in all scientific matters which it now occupies and become the mere mouthpiece of a clique.

What the Editor can do and has endeavoured to do in this case, is to guard the reputations of men of Science against the attacks of men of straw, and to see that no personalities are used; and it is under strong protest that he allows to pass in Prof. Tyndall's letter, for the reasons already stated, personalities, the equivalents of which, the Editor, in the exercise of his "undoubted editorial rights," struck out of Prof. Tait's communication.—ED. NATURE.]

* This tallies with Forbes's own account (Travels, page 38). "Far from being ready to admit, as my sanguine companions wished me to do in 1841, that the theory of glaciers was complete, and the cause of their motion certain, after patiently hearing all they had to say, and reserving my opinion, &c." This reservation of opinion is probably the reticence referred to by Agassiz.

NOTES FROM THE "CHALLENGER"

VII.

ON Monday the 30th of June we sounded in 1,000 fathoms, about 114 miles westward from Fayal. The dredge was put over early in the forenoon, and came up half filled with a grey sandy ooze with a large proportion of the dead shells of Pteropods, many Foraminifera, and many pebbles of pumice. Many animal forms of great interest were found entangled in the swabs, or sifted out of the mud. Another Schizopod crustacean of large size and great beauty of form and brilliancy of colouring came up in this haul. Dr. von Willemoes-Suhm regards it as congeneric with the species taken at Station 69, at a depth of 2,200 fathoms, and as these crustaceans are among our most interesting acquisitions during the voyage between Bermudas and the Açores, I will abstract a brief description of them from his notes.

Fig. 1.—Ophioglypha bullata, Wy. Thomson—six times the natural size.

The two crustaceans for whose reception Dr. von Willemoes-Suhm proposes to establish the genus *Gnathophansia* present characters which have hitherto been found partly in Schizopods and partly in Phyllopods, but not combined in the same animal. They are, however, essentially Schizopods, and have much in common with *Lophogaster*, a genus described in great detail by the late Prof. Sars. It is proposed to refer *Gnathophansia* to the family Lophogastridæ, which must be somewhat modified and expanded for its reception.

Fig. 2

Fig. 2.—Flabellum alabastrum, H. N. M.

Fig. 3

Fig. 3.—Ceratotrochus nobilis, H. N. M.

In *Gnathophansia* the dorsal shield covers the thoracic segments of the body, but it is unconnected with the last five of these. The shield is prolonged anteriorly into a spiny rostrum. The stalked eyes are fairly developed in the ordinary position. There is an auxiliary eye on each of the maxillæ of the second pair.

The two species of the genus are thus distinguished: *G. gigas*, n. sp. (Figs. 4 and 5). Scale of the outer an-

tenna with five teeth; dorsal shield with the outer angles of its posterior border produced into spines; no posterior spine in the middle line; length 142 mm. Of this species one specimen was taken from a depth of 2,200 fathoms, with a bottom of Globigerina ooze, at Station 69, 400 miles to the west of the Açores.

G. zoëa, n. sp. (Fig. 6): Scale of the outer antenna with one tooth. A long central spine on the posterior border of the dorsal shield, but no lateral spines; length, 60 mm. A single specimen at the present station likewise from a bottom of Globigerina ooze.

On comparing the figures of these two species and of their anatomical details with that of *Lophogaster* given by Sars, one is struck by their great general similarity; but

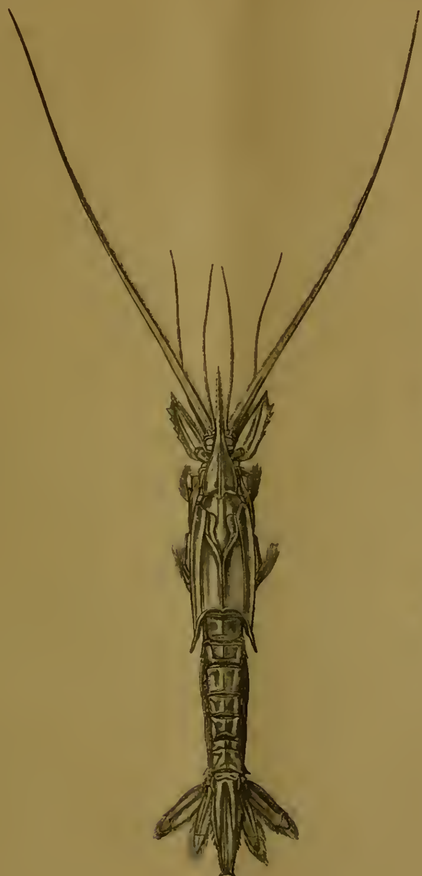

Fig 4

Fig 6

Fig. 5

Figs. 4 & 5.—Gnathophausia gigas, v. W.-S.

Fig. 6.—Gnathophansia zoea, v. W.-S.

there are characters presented by the new genus, particularly in connection with the dorsal shield, which not only entirely separate it from Lophogaster, but enlarge our views on the whole Schizopod group. In both species the shield is sculptured by ridges traversing it in different directions, and in both there is a long spiny rostrum; but this shield is merely a soft duplicature of the skin, connected with the body only anteriorly, and leaving five thoracic segments entirely free. In the structure of the shield and its mode of attachment *Gnathophausia* has the greatest resemblance to *Apus* among all crustaceans, but it differs from it widely in all other respects. *Nebalia* is the only Schizopod in which the carapace is not connected with the posterior thoracic segments, but in that genus the form of the carapace is totally different, and the genera are otherwise in no way nearly related.

Neither the antennæ, nor the scales, nor the parts of the mouth present any marked differences from those of

Lophogaster, with the exception of the second maxillæ. These, with nearly the same form as in the Norwegian genus, bear a pair of accessory eyes. Such eyes are well known at the base of the thoracic and even of the abdominal limbs in the Euphansidæ, a family with which the Lophogastridæ have otherwise nothing in common, but hitherto they have not been met with in any other animal or in any of the manducatory organs.

Of the eight pairs of legs seven are ambulatory, only the first pair is, as in *Lophogaster*, transformed into maxillipeds. The gills are arborescent and attached to the bases of the legs. The abdomen and its appendages scarcely differ from those of *Lophogaster*. We find here also that the last segment is apparently divided into two. This would indicate an approach to such forms as *Nebalia*, which has nine abdominal segments, or at all events a tendency to a multiplication of segments which if really existing would scarcely allow the association of the genus with the true Schizopods.

The weather was remarkably fine. During the day the island of Flores was visible like a cloud on the horizon, about 50 miles to the northward. In the afternoon we obtained a series of temperature soundings at intervals of 100 fathoms down to 1,000, and in the evening proceeded under steam towards Fayal.

On the following day, the 1st of July, we sounded in 1,350 fathoms, about 20 miles west of Fayal, apparently in a depression which separates the western group of the Açores, Flores and Corvo from the central group Fayal, Pico, San Jorge, Terceira, and Gracioza, and during the afternoon we gradually approached the fine island of Fayal, and enjoyed the development of its bold outlines and rich and varied colouring. In the evening we passed into the narrow channel between Fayal and Pico, and anchored in the roadsteads of Hortes. We found to our great disappointment that small-pox was prevalent in Fayal, and as Captain Nares considered it imprudent to give general leave, one or two of us only landed to pick up what general impression we might of the appearance of the place, and on the following morning we proceeded towards San Miguel, first taking a few hauls of the dredge in shallow water between Fayal and Pico, where we found a rather scanty fauna, resembling in character that of southern Europe, on a bottom of dark volcanic sand.

On Friday, July 4, we sounded in 750 fathoms on a rocky bottom. The ship water-bottle was sent down and brought up a sample of the bottom water. In the afternoon we shortened and furled sails, and proceeded under steam towards San Miguel, and in the evening stopped abreast of Ponta Delgada, the capital of the island, where we lay-to for the night, secured to a buoy. Next morning, as we found, greatly to our satisfaction, that the town was considered free from any epidemic of small-pox, we steamed in to the anchorage, and cast anchor in 13 fathoms.

We remained at San Miguel until Wednesday the 9th. We were well aware that the time at our disposal was quite insufficient to enable us to do anything of importance to add to the knowledge of the natural history of the island already so well worked out, and as we had had a long sea-cruise, we were in no way disinclined for a few days of complete relaxation. We accordingly combined into a large party, totally unscientific in its object, and by the aid of mules and donkeys made a most enjoyable raid among the caldeiras and volcanic ranges of the east end of the island. The random impressions collected during these *horæ subsecivæ* may perhaps be chronicled elsewhere.

Our first haul after leaving Ponta Delgada, was in 1,000 fathoms, mid-way between the islands of San Miguel and Santa Maria, and about fifteen miles north-west of the Formigas. The bottom was Globigerina ooze. The principal feature in this dredging was the unusual abundance of stony corals of the deep-sea group.

Two living specimens of a large species of *Flabellum* were sifted out, the same as the one which we had dredged previously at station 73, to the west of Fayal. The corallum is wedge-shaped, the calicle rising from an attenuated pedicle. The extreme height, from the end of the pedicle to the margin of the cup, is 50 mm.; the greatest diameter of this calicle is 65 mm., and the smallest 30 mm. The three species are very nearly of the same dimensions.

The lateral costæ make an angle with one another of 120° to 140°, and are sharp and moderately prominent, with an irregular edge. The external surface of the calicle is covered with a glistering epitheca, and near the margin is of a light pink colour. The costæ of the faces corresponding to the primary and secondary septa are almost as well marked as the lateral costæ, and appear as irregularly dental ridges, separated by slight depressions. The ends of the calicle are broadly rounded, and it is compressed laterally in the centre. The upper margin is curved, describing about one-third of a circle.

There are six systems of septa disposed in five cycles. The septa are extremely thin and fragile. They are tinged with pink, and covered with rounded granules, disposed in rows. The primary septa are approximately equal to the secondary, giving somewhat the appearance of twelve systems. These septa are broad and prominent, with a rounded superior margin, and curved lines of growth. The septa of the third, fourth, and fifth cycles successively, diminish in breadth, and are thus very markedly distinguished from one another, and from the primary and secondary septa. The septa of the fourth cycle join those of the third a short distance before reaching the columella. The septa of the fifth cycles are incomplete. The margin of the calicle is very deeply indented, the costal corresponding to the primary and secondary septa being prolonged in conjunction with the outer margins of these septa, into prominent pointed processes; similar but shorter prolongations accompany the tertiary, and some of the quaternary septa. Between each of the sharp projections thus formed, the edge of the wall of the calicle presents a curved indentation.

Two of the specimens procured, expanded their soft parts when placed in sea-water. The inner margin of the disc round the elongated oral aperture, presents a regular series of dentations, corresponding with the septa, and is of a dark madder colour; the remainder of the disc is pale pink. The tentacles take origin directly from the septa. They are elongated and conical. Those of the primary and secondary septa are equal in dimensions, and along with the tertiary tentacles, which are somewhat shorter, but in the same line, are placed nearest the mouth, and at an equal distance from it. The tentacles of the fourth and fifth cycles are successively smaller and at successively greater distances from the mouth. Placed on either side of each tentacle of the fifth cycle, and again somewhat nearer the edge of the calicle, there are a pair of very small tentacles which have no septa developed in correspondence with them. There are thus four successive rows of tentacles, and the normal number is ninety-six. The tentacles are of a light red colour, and between their bases are stripes of yellowish red and light grey.

This group belongs to the group *Flabella sub-pedicellata* of Milne-Edwards, and probably to that division in which the costæ are prominent and ridge like on the faces of the corallum, as well as on its lateral margins, but it differs from those described under this head by Milne-Edwards, in that it has five cycles, the fifth being incomplete, and in other particulars which appear from the description given.

A single living specimen of a coral referred by Mr. Moseley to the genus *Ceratotrochus* was obtained from this haul. The corallum is white. The base sub-pedicellate with a

small scar of original adherence. The principal costals are prominent, and round the region of the base beset with small spines directed somewhat upwards. The upper portion of the costa is without spines. The primary and secondary septa are broad and exsert. Pali are absent, the columella is fascicular. The absence of pali, the form of the columella, and the nature of the base, associate this form with the *Ceratrotrochi*, as defined by Milne-Edwards.

The animal is of a dark madder colour on the region of the margin of the calicle between the exsert primary and secondary septa, and on the membrane investing the wall of the corallum from the margin down to the commencement of the spines. This dark colour is succeeded on the disc by a band of pale bluish, within which there is again a zone of very dark madder colour round the mouth. The dark colouring-matter is interesting, as it gives an absorption spectrum of three distinct bands.

On Friday, July 11, we sounded in 2,025 fathoms, 376 miles to the west of Madeira, the bottom very well marked "globigerina ooze," and the bottom temperature 1° 5′ C.

The weather for the last few days had been remarkably fine, with a pleasant light breeze. When we turned up on deck on the morning of the 16th, we were already at anchor in the beautiful bay of Funchal, and looking at the lovely garden-like island, full of anticipations of a week's ramble among the peaks and "currals" and the summer "quintas" of our friends—anticipations which were doomed to be disappointed.

WYVILLE THOMSON

THE INTERNATIONAL METRIC COMMISSION AT PARIS

IN continuation of the notices of the proceedings of this Scientific Commission (see NATURE, vol. vii. p. 237), it may now be stated that the French Section have been engaged during the present year in the work of the Commission entrusted to them, and have continued their sittings up to the present time. It appears from the printed "Procès Verbaux" that their attention has been principally directed to the further investigations and experiments required for the melting and casting of the large mass of alloy of platinum and iridium, determined upon as the material of all the new standards, with the view of obtaining a homogeneous ingot of these two metals in the proper proportions. This preliminary work is now so far completed that the twelve members of the Commission elected as the Permanent Committee, have been summoned to meet at Paris on October 1, to consult upon the subject with the French Section, and more particularly to discuss and decide the following points :—

1. The date of the definitive of the melting platinum-iridium intended for the construction of the new International metric standards.

2. The question whether the *Mètres-à-bouts* requested by some countries shall be constructed from the metal of the same melting as the *Mètres-à-traits.*

3. Whether the kilograms shall be made from the metal of the same melting as the *Mètres-à-traits.*

As to the number of metric standards required to be constructed by the Commission, the greater number of the Governments represented at the Commission have already intimated their wishes to have in all 31 metres and 24 kilograms. Germany and Italy have not yet notified their decision. Austria and Switzerland have declined to reply until the question of the creation of an International Bureau is satisfactorily settled, and it is understood that the same course is being followed by Germany. Russia is favourable to the creation of the Bureau, but has not yet decided on the number of standards she will require.

In addition to the number of fifty delegates already appointed by twenty-nine Governments to take part in the International Metric Commission, and whose names have been already announced, the Haytian Government has nominated M. Ch. Laforestie, Chargé d'Affaires of the Haytian Republic, and the Government of Brazil has nominated Prof. Such de Capanema as their respective delegates of the Commission. The French Government has also invited the Governments of Central America, Persia, China, and Japan to send delegates to take part in the proceedings of the Commission.

As it will be expedient to construct a number of spare copies of the new metric standards, it will probably be necessary to prepare for the construction of not less than fifty metres and nearly as many kilograms.

But difficulties must inevitably and at once arise at Paris from the course taken by the Governments of Germany, Austria, and Switzerland, as it tends materially to impede the attainment of the declared primary objects of the Commission to construct and furnish every Government interested with uniform metric standards, which are to be accurately verified, and of equal authority. After the expiration of four years from the date of the appointment of the Commission by the French Government, on September 2, 1869, and the passing of almost unanimous resolutions at a full meeting of the Commission in 1872, upon the mode of constructing the new standards, the time has now arrived when everything has been got ready for commencing the actual construction of the new standards. It can hardly be expected that this, the real work of the Commission, is to be stopped until the ulterior question of the creation of an International Metric Bureau is settled to the satisfaction of the three above-mentioned Governments. Nor does a further significant step which has been recently taken by the Austrian Government lead to much hope of a satisfactory solution of this question.

The Austrian Government has officially declared th t it accepts in principle the establishment of an International Metric Bureau upon the basis of the resolutions passed by the Commission, so far as relates to the objects and functions of this Bureau ; and that it is quite disposed to take part in a Convention upon the subject, provided that all the other Governments represented at the Commission give their adherence. But it expressly reserves the right of making new propositions when the questions of the organisation, the seat, and the direction of the Bureau are discussed, as well as the right of definitively approving the Convention.

It proposes, at the same time, that in order to maintain the international character of the negociation, the seat of the Conference shall be at Berne, where the International Telegraphic Conference is now held, or at Brussels, these two cities being equally upon neutral territory.

And that for facilitating the proceedings of the Conference, the Permanent Committee appointed by the Metric Commission, shall previously elaborate a project of Convention to be communicated to the several governments interested ; and that the Conference be not convoked for completing the definitive Convention until the preliminary negociations shall be sufficiently advanced to allow of a favourable result.

The invitation given by the French Government to the Austrian and other governments, was to take part in the creation of the International Metric Bureau based upon the five points proposed by the Commission, and it now appears that Austria objects to three out of these five points. And even as regards the other two points, Austria's adhesion is conditional upon the concurrence of all the other governments represented at the Commission. Up to the present time, however, the governments of five countries only have officially notified their concurrence, whilst those of twelve countries have formally declined to take any part in the establishment of the proposed International Metric Bureau. Under these circumstances, its creation at all seems very problematical, however desirable it may be in the interests of metrological science.

It is evident that the decision upon these new propositions must be left entirely to the governments interested. At any rate, the discussion of the Austrian propositions appear to be quite beyond the powers of either the French Section or the Permanent Committee, who are in no way authorised to re-open questions which, so far as the action of the Commission is concerned, have already been unanimously decided at the full meeting of the Commission. Meanwhile, the specific work of the Commission must be proceeded with, and the approaching meeting at Paris will enable the final decisions to be made, which alone are now required for beginning the construction of the new Standards.

H. W. CHISHOLM

NOTES

AN election will be held on Thursday, October 30, to two fellowships in connection with Merton College, Oxford. The examination for one of these fellowships will be in mathematics, for the other in physical science. The election to the physical science fellowship will be decided with respect to proficiency in physics, but candidates will have an opportunity of showing a knowledge of chemistry as supplementary to physics. The examination in both these subjects will be partly practical, partly by papers, and will be held in common with Magdalen College. A lectureship in physics, tenable for three years, in Trinity College, of 200*l*. per annum, will be offered to the Fellow to be elected. The examination for the two fellowships will commence on Tuesday, October 7, at 9 A.M., in the Merton College Hall. Candidates are required to call on the Warden on Tuesday, October 7, between 4 and 5 P.M.

THE Opening Address of this session of the St. Thomas Charterhouse Teachers' Science Classes will be delivered by Mr. F. C. Buckmaster on Saturday morning, the 20th inst., at 10.30. The chair will be taken by Sir J. Bennett, and a deputation from the Science Department of South Kensington will attend. Last year this undertaking met with signal success: above 200 teachers of primary schools availed themselves of the privileges offered by the institution. Many of the late students are now qualified to give instruction in elementary science. The movement is likely to do an immense amount of good in the way of making the teaching of elementary science common amongst the masses. During the recess about 250*l*. has been expended in fitting up a chemical laboratory and purchasing scientific apparatus; this, together with the engagement of an additional number of lecturers, it is thought will again secure a large number students.

WE understand that the bryological books and exceedingly rich and important collections and preparations of mosses left by the late Prof. Sullivant, whose death we recorded last week, are consigned to the Grey Herbarium of Harvard University, with a view to their preservation and long continued usefulness. The remainder of his botanical library, his choice microscopes, and other collections are bequeathed to the State Scientific and Agricultural College just established at Columbus.

THE *American Naturalist* for August records the death of four contributors to that journal, all more or less known as working naturalists:—Prof. John Lewis Russell, of Salem, one of the founders, and for many years president of the Essex County (Massachusetts) Natural History Society, which afterwards became part of the Essex Institute, an active worker in botany; Mr. George Gibbs, of New Haven, the distinguished American ethnologist and philologist, whose special work had been in the language and history of the North American Indians; Col. John W. Foster, president of the Chicago Academy of Science, a constant contributor of papers and memoirs on geological and archæological subjects, and joint author with Prof. Whitney of the Government Report on the Mineral Lands of Lake Superior, published in 1850; and Prof. Henry James Clark, of Amherst, one of the most thorough histologists and best microscopists in the country, and a large contributor to Prof. Agassiz's volumes on the Natural History of the United States. Of these losses to science, Prof. Clark was under 50, and only Prof. Lewis over 60.

THE first meeting of the Agassiz Natural History Club, recently organised by the students of the Anderson School of Natural History on Penikese Island, was held on July 24, and showed signs of great energy and activity. Although the school had only been open a fortnight, lectures on surface geology, the embryology of vertebrates and articulates, on physiology, physical geography, on the microscope and its construction, with practical lessons on its use; free hand drawing on the blackboard, zoological and landscape drawing, and daily dredging excursions in the yacht *Sprite*, together with instructions in collecting and preserving animals, have been given. The amount of laboratory work done is stated to be most satisfactory. Large aquaria are being set up in the temporary laboratory.

THE Council of the Pharmaceutical Society are desirous of forming a complete herbarium of medical plants from every quarter of the globe, whether officinal or not. Mr. Holmes, the Curator of the Society's Museum, 17, Bloomsbury Square, will be glad to enter into communication with any foreign botanists and pharmaceutists willing to co-operate in the work.

IN a telegram from St. Petersburg, September 11, it is stated that General Kaufmann reports that the Amoo Daria river is not navigable by steamboats. The scientific expedition sent out by General Kaufmann to explore the old bed of the Amoo Daria river as far as the lake of Lara Kamish, returned on July 23 to the camp at Kunurgentsch. The expedition explored the river to a distance of 450 versts, and succeeded in collecting much valuable information and scientific materials.

IN a telegram from St. John's, Newfoundland, of September 11, it is stated that the *Juniata* had arrived there and reported that the camp of the crew of the *Polaris* was discovered by the *Tigress* on August 14 at Littleton Island, where the ship was deserted. Manuscript records of the expedition up to a period of six weeks before the discovery were secured. The *Tigress* is still in search of the Buddington party, who are believed to be safe.

A PAPER in Petermann's *Mittheilungen* upon the driftwood found in Nova Zembla has at present a special interest in connection with the discovery of fragments of a similar character by the crew of the *Polaris* in Polaris and Newman Bays. The Nova Zembla specimens consisted mainly of willow of various thicknesses. There were also, however, pieces of beech nearly a foot in diameter, several species of pine, among these *P. sylvestris*, an *Abies*, &c. It is thought that a large portion of this material must have been derived from the Petschora, Ob, and Yenesei rivers, and that none of it could have been derived from the current of the Gulf Stream.

THE past winter was very mild in the southern portion of Iceland, but quite severe in the northern. In the middle of January an eruption of the volcanoes in the great Yokul Mountains, in the south-east corner of the island, took place, which continued with unusual violence for about a week, and then suddenly ceased. Since then no fire has been noticed. Large quantities of ashes have fallen on different localities, but it is believed that the deep bed of snow protected the pasture lands from destruction. Volcanic eruptions took place at the same time in Chili.

The recent number of *Petermann's Mittheilungen* contains articles and maps on the American North Polar Expedition and Transcaspian Russia. The New Lybian Expedition and the Russian March on Khiva are the subjects of two of the articles.

By the death of the last surviving porpoise the Brighton Aquarium has to lament the loss of one of its most attractive features.

We have received the Prospectus of a new club to be called "The Scientific Societies Club." The approaching concentration of scientific societies, the Prospectus says, suggests that the present is a fitting time for the formation of a "Scientific Societies Club," (which would afford in the neighbourhood of Burlington House, conversation and reading rooms, as well as the usual facilities of a club for members of all scientific societies. In order to render the club generally available and as useful as possible to the scientific world, it is proposed that the entrance fee and the annual subscription shall each be small.

According to Dr. Fritsch, the discovery has lately been made of lacustrine dwellings in the vicinity of Leipsic, as the result of certain engineering operations undertaken to regulate the course of the River Elster. After passing through a series of layers at a certain depth, the workmen found a series of oak piles pointed below and decomposed above, and supporting a certain number of oak trunks placed horizontally; and on the same level with these were found certain lower jaws and teeth of oxen, fragments of antlers, broken bones of various mammifers, shells of an Anodon, fragments of pottery, two polished stone hatchets, &c.

Prof. C. A. White, of Iowa State University, and State geologist of Iowa, has been appointed to the new chair of Geology and Natural History at Bowdoin College.

A communication has been made to the Academia dei Lincei of Rome, by M. Tarry, giving the results of his personal experience and investigations into the connection between the cyclonic storms and the showers of sand that frequently visit Southern Europe. M. Tarry, after travelling as secretary to the French Meteorological Society into Northern Africa and the Desert of Sahara, and having consulted the files of the *Daily Weather Bulletin* of the Paris Observatory, believes himself to have established the fact that whenever a cyclone passes southward from Europe over the Mediterranean Sea into Africa (as some few of them do every season), it then returns northward or northwestward, and transports the sand which in the desert formed a sand-storm to the southern coasts of Europe as a sand-shower of greater or less duration. The satisfactory investigation of this subject is much impeded by the absence of barometric observations on the southern shores of the Mediterranean; and to remedy this defect, M. Tarry has recently established new meteorological statistics at Mogadore, Morocco, Terceira, Madeira, and even in the interior of the Sahara.

"General Remarks on the Climate of Bombay, with a brief description of the Peculiarities of the Weather of the year 1871," is the title of a pamphlet which we have just received, written by Mr. Charles Chambers, F.R.S., Superintendent of the Kolaba Observatory.

The *Times of India* states that education is making rapid progress in Ceylon, and vernacular schools will soon be within the reach of every section of the native community. The same paper states that Ceylon will contribute a selection of colonial products to the next Exhibition at South Kensington.

The Rev. Thos. Garnier, Dean of Winchester, who died recently at the age of 98, was the "father" of the Linnean Society, having been elected during the last century, in 1798, only ten years after the foundation of the Society. Some of his contributions to botanical literature bore the date of last century.

The additions to the Zoological Society's Gardens during the past week include a Garnet's Galago (*Galago garnetti*) from East Africa, presented by Capt. Geo. Butchart; a Manx Shearwater (*Procellaria puffinus*), British, presented by Dr. Bree; a Reeve's Muntjac (*Cervulus reevesi*), from China, presented by Mr. R. Swinhoe; a Spotted Cavy (*Cœlogenys paca*), from South America, presented by Mr. J. de Castro; three Common Chameleons (*Chamæleon vulgaris*), from Africa, presented by Mr. W. C. Hotham; an Alligator (*Alligator sp.*), presented by Mr. W. Gillespie.

SOCIETIES AND ACADEMIES

Paris

Academy of Sciences, Sept. 8.—M. Bertrand in the chair.—The following papers were read:—Fifth note on Guano, by M. Chevreul.—Note on the observations of M. Lecoq de Boisbaudran, relative to the appearance of Phylloxera in the vineyards of the Charente, by M. Milne-Edwards.—Note on the number of points of intersection which represent a multiple point common to two plane curves, &c., by M. de la Gournerie.—Researches on Crystalline Dissociation, continuation by MM. P. A. Favre and C. A. Valson. This portion of the paper dealt with the valuation and division of the work done in saline solutions.—Note on a New System of representing the continuous Meteorological Observations, made at the National Observatory, Algiers, by M. Bulard.—Note on Magnetism, third part, by M. J. M. Gaugain.—On the Spontaneous Motion of Ascension of Liquids in Capillary Tubes, by C. Decharme. This portion of the paper treated of the subject from a theoretical point of view.—On Pyrogallol in the presence of iron salts, by M. E. Jacquemin.—Researches on the Spectra of Chlorophyll, by M. J. Chautard. The author has found that this substance so easily changed as viewed from the physiological point of view, is very stable when subjected to chemical reagents.—On the state of the Volcano of Nisiros, in March, 1873, by M. H. Gorceix.—M. de Laval sent a note stating that he was the original proposer of the use of the carbonic disulphide against the Phylloxera.—The ephemerides of Brorsen's Comet were received from Mr. Plummer, and a note on the same comet, and on that of Faye, from M. Stephan.—New observations on the presence of Magnesium on the Solar Limb, and an answer to certain points in M. Faye's theory, by Father Tacchini. The author stated in his letter that the fact of the line 1474 K always appearing with *b*, and even without it, induces him to think that the former is not due to iron which is much heavier than magnesium.—On the use of Chronometers at sea, by M. Magnac.—Reflections on Spontaneous generation, in relation to a note by M. Gayon, on the spontaneous changes of eggs, and a note of Mr. Grace Calvert on the power of preventing the development of Protoplasmic life, by M. A. Béchamp.

THE BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE

The forty-third meeting of the Association was opened yesterday evening in Bradford, when Dr. Carpenter resigned the Presidency, and was succeeded by Prof. A. W. Williamson, who delivered the opening address in St. George's Hall.

Notwithstanding that Bradford is considerably larger than Brighton, its resources in the way of sleeping accommodation have been considerably tried by the unusually large influx of visitors caused by the meeting of the Association. All the hotels, we believe, are full, as well as most of the private houses on the lists of the secretaries. Arrangements have, however, been made with the railway companies for conveying members to and from neighbouring towns where hotel accommodation may be obtained. The local secretaries, Dr. Campbell, Mr. Goddard, and Mr. Peile Thompson, have spared no pains to make the

arrangements for the reception of the members of the Association perfect ; and if the meeting is not in all respects a complete success, it will be no fault of theirs, nor of the local authorities, who seem anxious to do all in their power for the comfort and enjoyment of the visitors.

A very fine town-hall was opened in Bradford a few days ago, but so far as we can learn, none of the meetings of the Association will be held in it. Ample accommodation has been provided in other buildings for the various meetings. The Sections met to-day at 11 A.M., and continue to do so till Tuesday next. Section A meets in the School Room, Horton Lane Chapel ; Section B in the School Room, Unitarian Chapel ; Section C in the Lecture Hall, Horton Lane Chapel ; Section D in the Church Institute ; Section E in the Mechanics' Institute ; Section F in the West Riding Court House ; and Section G in the Church Institute. To-night a *soirée* will be held in St. George's Hall : in the same place, to-morrow night, at 8 30, Professor W. C. Williamson, F.R.S., of Manchester, delivers a discourse on "Coal and Coal Plants ;" on Saturday evening, at 7.30, Dr. Siemens gives a lecture to the operative classes on "Fuel ;" and on Monday evening, at 8.30, Professor Clerk-Maxwell, a discourse on "Molecules." On Tuesday next, a *soirée* takes place at 8.30 P.M. in the Mechanics' Institute, where, on Wednesday, the concluding General Meeting will take place at 2.30 P.M. ; on the same evening, a Grand Complimentary Concert will be given in St. George's Hall, at 8 o'clock.

A number of Reports, both those involving and those not involving grants of money, will be given in, and will no doubt be listened to with great interest by the scientific men present. We hope that this year the Association will rise to the occasion in the matter of liberality, and give a practical example of what ought to be done in the endowment of scientific research. By the courtesy of the officers we are enabled to give the Inaugural and some of the Sectional Addresses. To the same source we are indebted for the following list of some of the papers to be read in the various sections :—

SECTION A.—Lord Rayleigh : A short paper on a Natural Limit to the Sharpness of the Spectral Lines.—W. Davis : Some Abnormal Effects of Binocular Vision.—H. Muirhead : On Regelation.—G. M. Whipple : A new Electrical Anemograph ; a new form of Rutherford's Minimum Thermometer ; on the Passage of Squalls across the British Isles.—W. R. Birt : On the Importance and Necessity of continued Systematic Observation of the Moon's Surface.—G. O. Hanlon : Some Suggestions towards the formation of extended Tables of Logarithms.—M. Hermite : On the Irrationality of the Base of Hyperbolic Logarithms.—R. S. Ball : Dynamometers for the Measurement of Force in absolute units ; A quiescent rigid body possessing three degrees of freedom receives an impulse : determine the instantaneous screw about which the body commences to twist.

SECTION B.—Messrs. A. Vernon Harcourt and F. W. Fish : On a continuous process for purifying Coal Gas from Sulphuretted Hyd. and Ammonia, and for extracting Sulphur and Ammoniacal Salts.—W. H. Pike : On several Homologues of Oxalic Acid.—Dr. Gladstone : Black Deposits of Metals.—C. Horner : On the Spectra of certain Boric and Phosphoric Acid blow-pipe beads.—J. Spiller : On Artificial Magnetite.—W. Symons : Remarks on a paper by the Marquis of Salisbury on Spectral Lines of Cold Temperature.—A. Tribe : Spec. gr. bottle for liquids spontaneously inflammable in contact with air.

SECTION C.—Rev. J. F. Blake : Additional Remains of Pleistocene Mammals in Yorkshire.—W. Blandford : Some Evidences of Glacial Action in Tropical India.—A. Leith Adams : Concluding Report of the Malta Fossil Elephants.—R. Russell : Geological Sketch of Bradford and the neighbourhood.—J. Hopkinson : On Graptolites found (1) in Ramsay Island, St. David's ; (2) in the Ludlow Rocks of Shropshire.—H. Hicks : On the Arenig and Llandeilo Rocks of St. David's.—J. L. Lobley : On the British Palæozoic Arcade.

SECTION D.—Hyde Clarke : Comparative Chronology of Man in America in relation to Comparative Philology.—Prehistoric Names of Weapons.—W. T. Blandford : The Fauna of Persia.—J. Willis : The Flora of the Environs of Bradford.—J. Milnes Fothergill : Heart and Brain.—K. Kaines : A true Cerebral Theory necessary to Anthropology.

SECTION E.—C. F. Beke : On the True Position of Mount Sinai.—W. Blandford : Physical Geography of the Deserts of Persia and Central Asia.—G. Darwin : On Some Maps of the World and on a Portable Globe.—Rev. W. B. Kerr : Overland Route from India.—E. L. Oxenham : A Journey from Pekin to Hankow.—Capt. Davis : The Voyage of the *Challenger*.—Sir F. Goldsmid : On Persia.

SECTION F.—Hyde Clarke : The Influence of Large Centres of Population on Intellectual Manifestation.—Dr. Appleton : On some of the Economical Aspects of Endowments of Education and Original research.—T. G. P. Hallett : The Income Tax Question.—W. P. Henderson : Commercial Panics.—W. Hastings : Postal Reform.—R. H. Palgrave : The Relation of the Banking Reserve of the Bank of England to the Current Rate of Interest.—G. C. T. Barnsley : The Poor-Law Board and its Effect on Thrift.

Among British men of science expected to be present at this year's meeting are the following :—Prof. W. G. Adams, F.R.S. ; Major-General Sir J. Alexander, Sir Rutherford Alcock, K.C.B. ; Prof. Attfield, Prof. R. S. Ball, Admiral Sir E. Belcher, K.C.B. ; W. H. Barlow, F.R.S. ; Prof. Balfour, W. Boyd Dawkins, F.R.S. ; Sir P. G. Egerton, F.R.S. ; Sir W. Fairbairn, F.R.S. ; Dr. W. Farr, Prof. Michael Foster, M.D. : Mr. J. G. Fitch, Mr. P. Le Neve Foster, Mr. C. L. N. Foster, Col. Lane Fox, Sir G. D. Gibb, Bart. ; Rev. Prof. Griffiths, Capt. D. Galton, C.B. ; G. Griffiths, F.C.S. ; Prof. Greenwood, Mr. J. W. L. Glaisher, Sir F. Goldsmid, J. P. Gassiot, F.R.S. ; Dr. J. H. Gladstone, F.R.S. ; Dr. P. H. Holland, W. Huggins, D.C.L., F.R.S. ; Prof. Hughes, Lord Houghton, F.R.S. ; Prof. G. Harley, F.R.S. ; Prof. Herschel, Rev. R. Harley, F.R.S. ; Mr. A. V. Harcourt, F.R.S. ; Mr. G. J. Holyoake, Mr. A. K. Johnston, Prof. Leone Levi, Prof. J. Clerk Maxwell, F.R.S. ; Prof. A. Newton, F.R.S. ; Vice-Admiral Ommaney, C.B., F.R.S. : Prof. Phillips, W. Pengelly, F.R.S. ; the Earl of Rosse, Prof. G. Rolleston, M.D., F.R.S. ; Prof. Roscoe, F.R.S. ; Dr. W. Rutherford, Dr. W. J. Russell, F.R.S. ; Prof. Savage, Prof. Balfour Stewart, F.R.S. ; Major-General Scott, Prof. Smith, Prof. Tyndall, F.R.S. ; Prof. W. C. Williamson, F.R.S. ; T. Wright, F.S.A. ; Prof. Williamson, F.R.S. ; the Archbishop of York, &c. The following foreigners are also expected to be present :—M. Guido Cora, Dr. Janssen, Prof. Klein, Baron von Richthofen, Arminius Vambery, &c.

INAUGURAL ADDRESS OF PROF. ALEXANDER W. WILLIAMSON, F.R.S., PRESIDENT.

INSTEAD of rising to address you on this occasion I had hoped to sit quietly amongst you, and to enjoy the intellectual treat of listening to the words of a man of whom England may well be proud—a man whose life has been spent in reading the great book of nature, for the purpose of enriching his fellow men with a knowledge of its truths—a man whose name is known and honoured in every corner of this planet to which a knowledge of science has penetrated—and, let me add, a man whose name will live in the grateful memory of mankind as long as the records of such noble work are preserved.

At the last meeting of the Association I had the pleasure of proposing that Dr. Joule be elected President for the Bradford Meeting, and our Council succeeded in overcoming his reluctance and in persuading him to accept that office.

Nobly would Joule have discharged the duties of President had his bodily health been equal to the task; but it became apparent after a while that he could not rely upon sufficient strength to justify him in performing the duties of the Chair, and, in obedience to the orders of his physician, he placed his resignation in the hands of the Council about two months ago. When, under these circumstances, the Council did me the great honour of asking me to accept their nomination to the Presidentship, I felt that their request ought to have with me the weight of a command.

For a good many years past Chemistry has been growing at a more and more rapid rate, growing in the number and variety of facts which are added to its domain, and not less remarkably in the clearness and consistency of the ideas by which these facts are explained and systematised. The current literature of chemical research extends each year to the dimensions of a small library; and mere brief extracts of the original papers published annually by the Chemical Society, partly aided by a grant from this Association, take up the chief part of a very stout volume. I could not, if I would, give you to-night even an outline of the chief newly discovered compounds and of the various changes which they undergo, describing each of them by its own name (often a very long one) and recording the specific properties which give to each substance its highest scientific interest. But I am sure that you would not wish me to do so if I could; for we do not meet here to study chemistry; I conceive that we meet here for the purpose of considering what this wondrous activity in our science means, what is the use of it, and, true to our object as embodied in the name of this Association, to consider what we can do to promote the Advancement of Science. I propose to lay before you some facts bearing on each of these questions, and to submit to you some considerations respecting them.

In order to ascertain the meaning of the work which has been going on in chemistry, it will, I think, be desirable for us to consider the leading ideas which have been in the minds of chemists, and which guide their operations.

Now, since the father of modern chemistry, the great Dalton, gave to chemists a firm hold of the idea of Atoms, their labours have been continually guided by that fundamental idea, and have confirmed it by a knowledge of more and more facts, while at the same time steadily adding to our knowledge of the properties of atoms. Every chemist who is investigating a new compound takes for granted that it must consist of a great number of atom-clusters (called by him molecules), all of them alike, and each molecule consisting of a certain number of atoms of at least two kinds. One of his first endeavours is to ascertain how many atoms of each kind there are in each molecule of the compound. I must not attempt to describe to you the various kinds of experiment which he performs for the purpose of getting this information, how each experiment is carried out with the aid of delicate instruments and ingenious contrivances found by long experience to enable him to obtain the most trustworthy and accurate results; but I want to draw your attention to the reasoning by which he judges of the value of such experiments when they agree among themselves, and to the meaning which he attaches to their result.

If the result of his experiments does not nearly agree with any atomic formula (that is, if no conceivable cluster of atoms of the kinds known to be in the compound would on analysis give such results as those obtained), the chemist feels sure that his experiments must have been faulty: either the sample of substance which he worked upon contained foreign matter, or his analyses were not made with due care. He sets to work again, and goes on till he arrives at a result which is consistent with his knowledge of the combining-properties of atoms. It is hardly necessary to say that even the best experiment is liable to error, and that even a result obtained with the utmost care cannot be expected to afford more than an approximation to the truth. Every good analysis of a pure compound leads to results which approximate to those required by the Atomic Theory; and chemists trust so thoroughly to the truth of that guide, that they correct the results of such analysis by the aid of it.

The chemical idea of atoms serves for two purposes:—

1. It gives a clear and consistent explanation of an immense number of facts discovered by experiment, and enables us to compare them with one another and to classify them.

2. It leads to the anticipation of new facts, by suggesting new compounds which may be made; at the same time it teaches us that no compounds can exist with their constituents in any other than atomic proportions, and that experiments which may imply the existence of any such compound are faulty.

We have the testimony of the great Berzelius to the flood of light which the idea of atoms at once threw on the facts respecting combining proportions which had been accumulated before it was made known; and from that time forward its value has rapidly increased as each succeeding year augmented the number of facts which it explained.

Allow me at this point of my narrative to pause for a moment in order to pay a tribute of respect and gratitude to the memory of one who has recently passed from among us, and who in the time of his full activity was a leader of the discoveries of new facts in the most difficult part of our science. Liebig has been generally known in this conntry through his writings on agricultural chemistry, through his justly popular letters on chemistry, and other writings, by means of which his brilliant intellect and ardent imagination stimulated men to think and to work. Among chemists he was famed for his numerous discoveries of new organic compounds, and their investigation by the aid of improved methods; but I believe that the greatest service which his genius rendered to science was the establishment of the chemical school of Giessen, the prototype of the numerous chemical schools for which Germany is now so justly celebrated. I think it is not too much to say that the Giessen laboratory, as it existed some thirty years ago, was the most efficient organisation for the promotion of chemistry which had ever existed.

Picture to yourselves a little community of which each member was fired with enthusiasm for learning by the genius of the great master, and of which the best energies were concentrated on the one object of experimental investigation.

The students were for the most part men who had gone through a full curriculum of ordinary studies at some other University, and who were attracted from various parts of the world by the fame of this school of research.

Most of the leading workers of the next generation were pupils of Liebig; and many of them have established similar schools of research.

We must not, however, overlook the fact that Liebig's genius and enthusiasm would have been powerless in doing this admirable work, had not the rulers of his Grand-Duchy been enlightened enough to know that it was their duty to supply him with the material aids requisite for its successful accomplishment.

Numberless new compounds have been discovered under the guidance of the idea of atoms; and in proportion as our knowledge of substances and of their properties became more extensive, and our view of their characteristics more accurate and general, were we able to perceive the outlines of their natural arrangement, and to recognise the distinctive characteristics of various classes of substances. I wish I could have the pleasure of describing to you the origin and nature of some of these admirable discoveries, such as homologous series, types, radicals, &c.; but it is more to our purpose to consider the effect which they had upon the idea of atoms, an idea which, still in its infancy, was plunged into the intellectual turmoil arising from a variety of novel and original theories suggested respectively by independent workers as best suited for the explanation of the particular phenomena to which their attention was mainly directed.

Each of these workers was inclined to attach quite sufficient importance to his own new idea, and to sacrifice for its sake any other one capable of interfering with its due development.

The father of the atomic theory was no more; and the little infant had no chance of life, unless from its own sterling merits it were found useful in the work still going on.

What then was the result? Did it perish like an ephemeral creation of human fancy? or did it survive and gain strength by the inquiries of those who questioned Nature and knew how to read her answers?

Although anticipating my answer to these questions, you will probably be surprised to hear the actual result which I have to record, a result so wonderful that the more I think of it the more I marvel at it. Not only did these various theories contain nothing at variance with the atomic theory; they were found to be natural and necessary developments of it, and to serve for its application to a variety of phenomena which were unknown to its founder.

Among the improvements of our knowledge of atoms which have taken place, I ought to mention the better evaluations of the relative weight of atoms of different kinds, which have been made since Dalton's time. More accurate experiments than

those which were then on record have shown us that certain atoms are a little heavier or lighter than was then believed, and the work of perfecting our observations is constantly going on with the aid of better instruments and methods of operation. But, apart from these special corrections, a more sweeping change has taken place, not in consequence of more accurate experiments interpreted in the usual way, but in consequence of a more comprehensive view of the best experimental results which had been obtained, and a more consistent interpretation of them. Thus the atomic weight of carbon had been fixed at 6 by Dumas's admirable experiments; and it was quite conceivable that a still more perfect determination might slightly increase or diminish this number. But those who introduced the more sweeping change asserted in substance that two of these supposed atoms, whatever may be the precise weight of each, always are together and never separate from one another; and they accordingly applied the term atom to that indivisible mass of carbon weighing twice as much as a carbon atom had been supposed to weigh. So also with regard to other elements, it has been shown that many atoms are really twice as heavy as had been supposed, according to the original interpretation of the best experiments. This change was brought about by what I may be permitted to call the operation of stock-taking. Dalton first took stock of our quantitative facts in a business-like manner; but the amount and variety of our chemical stock increased so enormously after his time, that the second stock-taking absorbed the labours of several men for a good many years. They were men of different countries and very various turns of mind; but, as I mentioned just now, they found no other fundamental idea to work with than Dalton's; and the result of their labours has been to confirm the truth of that idea and to extend greatly its application.

One of the results of our endeavours to classify substances according to their natural resemblances has been the discovery of distinct family relationships among atoms, each family being distinguished by definite characteristics. Now among the properties which thus characterise particular families of atoms, there is one of which the knowledge gradually worked out by the labours of an immense number of investigators must be admitted to constitute one of the most important additions ever made to our knowledge of these little masses.

I will endeavour to explain it to you by a simple example. An atom of chlorine is able to combine with one atom of hydrogen or one atom of potassium; but it cannot combine with two atoms. An atom of oxygen, on the other hand, can combine with two atoms of hydrogen or with two atoms of potassium, or with one atom of hydrogen and one of potassium; but we cannot get it in combination with one atom of hydrogen or of potassium solely.

Again, an atom of nitrogen is known in combination with three atoms of hydrogen; while an atom of carbon combines with four of hydrogen. Other atoms are classified, from their resemblance to these respectively, as Monads, Dyads, Triads, Tetrads, &c.

The combining value which we thus recognise in the atoms of these several classes has led us naturally to a consideration of the order in which atoms are arranged in a molecule. Thus, in the compound of oxygen with hydrogen and potassium, each of these latter atoms is directly combined with the oxygen, and the atom of oxygen serves as a connecting link between them. Hydrogen and potassium have never been found capable of uniting directly with one another; but when both combined with one atom of oxygen they are in what may be called indirect combination with one another through the medium of that oxygen.

One of the great difficulties of chemistry some few years ago was to explain the constitution of isomeric compounds, those compounds whose molecules contain atoms of like kinds and in equal numbers, but which differ from one another in their properties. Thus a molecule of common ether contains four atoms of carbon, ten atoms of hydrogen, and one of oxygen. Butylic alcohol, a very different substance, has precisely the same composition. We now know that in the former the atom of oxygen is in the middle of a chain of carbon atoms, whereas in the latter it is at one end of that chain. You might fancy it impossible to decide upon anything like consistent evidence such questions as this; but I can assure you that the atomic theory, as now used by chemists, leads frequently to conclusions of this kind, which are confirmed by independent observers, and command general assent. That these conclusions are, as far as they go, true descriptions of natural phenomena is shown by the fact that each of them serves in its turn as a stepping-stone to further discoveries.

One other extension of our knowledge of atoms I must briefly mention, one which has as yet received but little attention, yet which will, I venture to think, be found serviceable in the study of the forces which bring about chemical change.

The original view of the constitution of molecules was statical; and chemists only took cognizance of those changes of place among their atoms which result in the disappearance of the molecules employed, and the appearance of new moleclules formed by their reaction on one another. Thus, when a solution of common salt (sodic chloride) is mixed with a solution of silver nitrate, it is well-known that the metallic atoms in these respective compounds change places with one another, forming silver chloride and sodic nitrate; for the silver chloride soon settles to the bottom of the solution in the form of an insoluble powder, while the other product remains dissolved in the liquid. But as long as the solution of salt remained undecomposed, each little molecule in it was supposed to be chemically at rest. A particular atom of sodium which was combined with an atom of chlorine was supposed to remain steadily fixed to it. When this inactive solution was mixed with the similarly inactive solution of silver nitrate, the interchange of atoms known to take place between their respective molecules was nominally explained by the force of predisposing affinity. It was, in fact, supposed that the properties of the new compounds existed and produced effects before the compounds themselves had been formed.

I had occasion to point out a good many years ago that molecules which appear to be chemically at rest are acting on one another, when in suitable conditions, in the same kind of way as those which are manifestly in a state of chemical change—that for instance, the molecules of liquid sodic chloride exchange sodium atoms with one another, forming new molecules of the same compound undistinguishable from the first, so that, in an aggregate of like molecules, the apparent atomic rest is the result of the interchange of like atoms between contiguous molecules. Such exchanges of atoms take place not only between molecules of identical composition, but also between contiguous molecules containing different elements. For instance, in a mixture of sodic chloride and potassic iodide an interchange of metallic atoms takes place, forming potassic chloride and sodic iodide. The result of the exchange in such a case is to form a couple of new molecules different from the original couple. But these products are subject to the same general law of atomic changes, and their action on one another reproduces a couple of molecules of the materials.

Thus a liquid mixture formed from two compounds contains molecules of four kinds, which we may describe as the two materials and the two products. The materials are reacting on one another, forming the products; and these products are, in their turn, reacting on one another, reproducing the materials.

If one of the products of atomic exchange between two molecules is a solid while the other remains liquid (as when sodic chloride is mixed with silver nitrate), or if one is gaseous while the other remains liquid, so that the molecules of the one kind cannot react on those of the other kind and reproduce the materials, then the continued reaction of the materials on one another leads to their complete mutual decomposition. Such complete mutual decomposition of two salts takes place whenever they react on one another under such conditions that the products cannot react on one another and reproduce the materials; whereas partial decomposition takes place whenever the materials form a homogeneous mixture with the products.

Now, if in any such homogeneous mixture more exchanges of atoms take place between the materials than between the products, the number of molecules of the products is increased, because more of them are being made than unmade; and reciprocally, if more exchanges of atoms take place between the products than between the materials, the number of molecules of the materials is increased. The mixture remains of constant composition when there are in the unit of time as many decomposing changes as reproducing changes.

Suppose that we were to determine by experiment the proportion between the number of molecules of the materials, and the number of molecules of the products, in a mixture the composition of which remains constant, and that we found, for instance, twice as many of materials as of products; what would this mean? Why, if every two couples of materials only effect in the unit of time as many exchanges as every one couple of pro-

ducts, every couple of materials is only exchanging half as fast as every couple of products.

In fact you perceive that a determination of the proportion in which the substances are present in such a mixture will give us a measure of the relative velocities of those particular atomic motions; and we may thus express our result:—The force of chemical combination is inversely proportional to the number of atomic interchanges.

I cannot quit this part of our subject without alluding to the fact that some few chemists, of such eminence as to be entitled to the most respectful attention, have of late years expressed an opinion that the idea of atoms is not necessary for the explanation of the changes in the chemical constitution of matter, and have sought as far as possible to exclude from their language any allusion to atoms.

It would be out of place on this occasion to enter into any discussion of the questions thus raised; but I think it right to point out:—

I. That these objectors have not shown us any inconsistency in the atomic theory, nor in the conclusions to which it leads.

II. That neither these nor any other philosophers have been able to explain the facts of chemistry on the assumption that there are no atoms, but that matter is infinitely divisible.

III. That when they interpret their analyses, these chemists allow themselves neither more nor less latitude than the atomic theory allows; in fact, they are unconsciously guided by it.

These facts need no comment from me.

Our science grows by the acquisition of new facts which have an intelligible place among our ideas of the order of nature; but in proportion as more and more facts are arranged before us in their natural order, In proportion as our view of the order of nature becomes clearer and broader, we are able to observe and describe that order more fully and more accurately—in fact, to improve our ideas of the order of nature. These more extensive and more accurate ideas suggest new observations, and lead to the discovery of truths which would have found no place in the narrower and less accurate system. Take away from Chemistry the ideas which connect and explain the multifarious facts observed, and it is no longer a science; it is nothing more than a confused and useless heap of materials.

The answer to our question respecting the meaning of the earnest work which is going on in our science must, I think, now be plain to you. Chemists are examining the combining properties of atoms, and getting clear ideas of the constitution of matter.

Admitting, then, for the present, that such is the meaning of chemical work, we have to consider the more important question of its use; and I think you will agree with me that, in order to judge soundly whether and in what manner such a pursuit is useful, we have to consider its effect upon Man. What habits of mind does it engender? What powers does it develop? Does it develop good and noble qualities and aspirations, and tend to make men more able and more anxious to do good to their fellow-men? Or is it a mere idle amusement, bearing no permanent fruits of improvement?

You will, I think, answer these questions yourselves if I can succeed in describing to you some of the chief qualities which experience has shown to be requisite for the successful pursuit of Chemistry, and which are necessarily cultivated by those who qualify themselves for such a career.

One of the first requirements on the part of an investigator is accuracy in observing the phenomena with which he deals. He must not only see the precise particulars of a process as they present themselves to his observation; he must also observe the order in which these particular appearances present themselves under the conditions of each experiment. No less essential is accuracy of memory. An experimental inquirer must remember accurately a number of facts; and he needs to remember their mutual relations, so that one of them when present to his mind may recall those others which ought to be considered with it. In fact, he cultivates the habit of remembering facts mainly by their place in nature. Accuracy in manual operations is required in all experimental inquiries; and many of them afford scope for very considerable skill and dexterity.

These elementary qualities are well known to be requisite for success in experimental science, and to be developed by careful practice of its methods; but some higher qualities are quite as necessary as these in all but the most rudimentary manipulations, and are developed in a remarkable degree by the higher work of science.

Thus it is of importance to notice that a singularly good training in the accurate use of words is afforded by experimental chemistry. Everyone who is about to enter on an inquiry, whether he be a first-year's student who wants to find the constituents of a common salt, or whether he be the most skilled and experienced of chemists, seeks beforehand to get such information from the records of previous observations as may be most useful for his purpose. This information he obtains through the medium of words; and any failure on his part to understand the precise meaning of the words conveying the information requisite for his guidance is liable to lead him astray. Those elementary exercises in analytical chemistry, in which brief directions to the students alternate with their experiments and their reports of experiments made and conclusions drawn, afford a singularly effective training in the habit of attending accurately to the meaning of words used by others, and of selecting words capable of conveying without ambiguity the precise meaning intended. Any inaccuracy in the student's apprehension of the directions given, or in the selection of words to describe his observations and conclusions, is at once detected when the result to which he ought to have arrived is known beforehand to the teacher.

Accuracy of reasoning is no less effectively promoted by the work of experimental chemistry. It is no small facility to us that the meaning of the words which we use to denote properties of matter and operations can be learnt by actual observation. Moreover each proposition comprised in chemical reasonings conveys some distinct statement susceptible of verification by similar means; and the validity of each conclusion can be tested, not only by examining whether or not it follows of necessity from true premisses, but also by subjecting it to the independent test of special experiment.

Chemists have frequent occasion to employ arguments which indicate a probability of some truth; and the anticipations based upon them serve as guides to experimental inquiry by selecting crucial tests. But they distinguish most carefully such hypotheses from demonstrated facts.

Thus a pale green solution, stated to contain a pure metallic salt, is found to possess some properties which belong to salts of Iron. Nothing else possesses these properties except salts of Nickel; and they manifest a slight difference from Iron salts in one of the properties observed.

The analyst could not see any appearance of that peculiarity which distinguishes Nickel salts; so he concludes that he has probably got iron in his solution, but almost certainly either Iron or Nickel. He then makes an experiment which will, he knows, give an entirely different result with Iron salts and Nickel salts; and he gets very distinctly the result which indicates Iron.

Having found in the green liquid properties which the presence of Iron could alone impart, he considers it highly probable that Iron is present. But he does not stop there; for, although the facts before him seem to admit of no other interpretation, he knows that, from insufficient knowledge or attention, mistakes are sometimes made in very simple matters. The analyst therefore tries as many other experiments as are known to distinguish Iron salts from all others; and if any one of these leads distinctly to a result at variance with his provisional conclusion, he goes over the whole inquiry again, in order to find where his mistake was. Such inquiries are practised largely by students of chemistry, in order to fix in their minds, by frequent use, a knowledge of the fundamental properties of the common elements, in order to learn by practice the art of making experiments, and, above all, in order to acquire the habit of judging accurately of evidence in natural phenomena. Such a student is often surprised at being told that it is not enough for him to conduct his experiments to such a point that every conclusion except one is contrary to the evidence before him—that he must then try every confirmatory test which he can of the substance believed to be present, and ascertain that the sample in his hands agrees, as far as he can see, in all properties of the known substance of which he believes it to be a specimen.

Those who tread the path of original inquiry, and add to human knowledge by their experiments, are bound to practise this habit with the most scrupulous fidelity and care, or many and grave will be the mistakes they will make.

Thus a chemist thinks it probable tha he might prepare some well-known organic body of the aromatic family by a new process. He sets to work and obtains a substance agreeing in appearance, in empirical composition, in molecular weight, and in many other properties with the compound which he has in view. He is, however, not satisfied that his product is a sample of that

compound until he has examined carefully whether it possesses all the properties which are known to belong to the substance in question. And many a time is his caution rewarded by the discovery of some distinct difference of melting-point, or of crystalline form, &c., which proves that he has made a new compound isomeric with the one which he expected to make. It seemed probable, from the agreement of the two substances in many particulars, that they might be found to agree in all, and might be considered to be the same compound; but complete proof of that conclusion consists in showing that the new substance agrees with all that we know of the old one.

In the most various ways chemists seek to extend their knowledge of the uniformity of nature; and their reasonings by analogy from particulars to particulars suggest the working hypotheses which lead to new observations. Before, however, proceeding to test the truth of his hypothesis by experiment, the chemist passes in review, as well as he can, all the general knowledge which has any bearing on it, in order to find agreement or disagreement between his hypothesis and the ideas established by past experience. Sometimes he sees that his hypothesis is at variance with some general law in which he has full confidence, and he throws it aside as disproved by that law. On other occasions he finds that it follows of necessity from some known law, and he then proceeds to verify it by experiment, with a confident anticipation of the result. In many cases the hypothesis does not present sufficiently distinct agreement or disagreement with the ideas established by previous investigations to justify either the rejection of it or a confident belief in its truth; for it often happens that the results of experience of similar phenomena are not embodied in a sufficiently definite or trustworthy statement to have any other effect than that of giving probability or the contrary to the hypothesis.

Another habit of mind which is indispensable for success in experimental chemistry, and which is taught by the practice of its various operations, is that of truthfulness.

The very object of all our endeavours is to get true ideas of the natural processes of chemical action; for in proportion as our ideas are true do they give us the power of directing these processes. In fact, our ideas are useful only so far as they are true; and he must indeed be blind to interest and to duty who could wish to swerve from the path of truth. But if anyone were weak enough to make the attempt, he would find his way barred by innumerable obstacles.

Every addition to our science is a matter of immediate interest and importance to those who are working in the same direction. They verify in various ways the statements of the first discoverer, and seldom fail to notice further particulars, and to correct any little errors of detail into which he may have fallen. They soon make it a stepping-stone to further discoveries. Anything like wilful misrepresentation is inevitably detected and made known.

It must not, however, be supposed that the investigator drifts unconsciously into the habit of truthfulness for want of temptation to be untruthful, or even that error presents itself to his mind in a grotesque and repulsive garb, so as to enlist from the first his feelings against it; for I can assure you that the precise contrary of these things happens. Error comes before him usually in the very garb of truth, and his utmost skill and attention are needed to decide whether or not it is entitled to retain that garb.

You will easily see how this happens if you reflect that each working hypothesis employed by an investigator is an unproven proposition, which bears such resemblance to truth as to give rise to hopes that it may really be true. The investigator trusts it provisionally to the extent of trying one or more experiments, of which it claims to predict the specific result. Even though it guide him correctly for a while, he considers it still on trial until it has been tested by every process which ingenuity can suggest for the purpose of detecting a fault.

Most errors which an experimentalist has to do with are really imperfect truths, which have done good service in their time by guiding the course of discovery. The great object of scientific work is to replace these imperfect truths by more exact and comprehensive statements of the order of nature.

Whoever has once got knowledge from Nature herself by truthful reasoning and experiment, must be dull indeed if he does not feel that he has acquired a new and noble power, and if he does not long to exercise it further, and make new conquests from the realm of darkness by the aid of known truths.

The habit of systematically searching for truth by the aid of known truths, and of testing the validity of each step by constant reference to Nature, has now been practised for a sufficiently long time to enable us to judge of some of its results.

Every true idea of the order of Nature is an instrument of thought. It can only be obtained by truthful investigation; and it can only be used effectively in obedience to the same laws. But the first idea which is formed of anything occurring in nature affords only a partial representation of the actual reality, by recording what is seen of it from a particular point of view. By examining a thing from different points of view we get different ideas of it; and when we compare these ideas accurately with one another, recollecting how each one was obtained, we find that they really supplement each other.

We try to form in our minds a distinct image of a thing capable of producing these various appearances; and when we have succeeded in doing so, we look at it from the different points of view from which the natural object has been examined, and find that the ideas so obtained meet at the central image. It usually happens that an accurate examination of the mutual bearings of these ideas on a central image suggests additions to them and correction of some particulars in them.

Thus it is that true ideas of a natural phenomenon confirm and strengthen one another; and he who aids directly the development of one of them is sure to promote indirectly the consolidation of others.

Each onward step in the search for truth has made us stronger for the work; and when we look back upon what has been done by the efforts of so many workers simply but steadily directed by truth towards further truth, we see that they have achieved, for the benefit of the human race, the conquest of a systematic body of truths which encourages men to similar efforts while affording them the most effectual aid and guidance.

This lesson of the inherent vitality of truth, which is taught us so clearly by the history of our science, is well worthy of the consideration of those who, seeing that iniquity and falsehood so frequently triumph for a while in the struggle for existence, are inclined to take a desponding view of human affairs, and almost to despair of the ultimate predominance of truth and goodness. I believe it would be impossible at the present time to form an adequate idea of the vast consequences which will follow from the national adoption of systematic measures for allowing our knowledge of truth to develop itself freely, through the labours of those who are willing and able to devote themselves to its service, so as to strengthen more and more the belief and trust of mankind in its guidance, in small matters as well as in the highest and most important considerations.

I am desirous of describing briefly the more important of those measures; but first let me mention another habit of mind which naturally follows from the effective pursuit of truth—a habit which might be described in general terms as the application to other matters of the truthfulness imparted by science.

The words which the great German poet put into the mouth of Mephistopheles when describing himself to Faust afford perhaps the most concise and forcible statement of what we may call the anti-scientific spirit:—

Ich bin der Geist der stets verneint,
Dem alles, was entsteht, zuwider ist.

The true spirit of science is certainly affirmative, not negative; for, as I mentioned just now, its history teaches us that the development of our knowledge usually takes place through two or more simultaneous ideas of the same phenomenon, quite different from one another, both of which ultimately prove to be parts of some more general truth; so that a confident belief in one of those ideas does not involve or justify a denial of the others.

I could give you many remarkable illustrations of this law from among ideas familiar to chemists. But I want you to consider with me its bearing on the habit of mind called toleration, of which the development in modern times is perhaps one of the most hopeful indications of moral improvement in man.

In working at our science we simply try to find out what is true; for although no usefulness is to be found at first in most of our results, we know well that every extension of our knowledge of truth is sure to prove useful in manifold ways. So regular an attendant is usefulness upon truth in our work, that we get accustomed to expect them always to go together, and to believe that there must be some amount of truth wherever there is manifest usefulness.

The history of human ideas, so far as it is written in the records of the progress of science, abounds with instances of men contributing powerfully to the development of important general

ideas, by their accurate and conscientious experiments, while at the same time professing an actual disbelief in those ideas. Those records must indeed have been a dead letter to any who could stand carping at the intellectual crotchets of a good and honest worker, instead of giving him all brotherly help in the furtherance of his work.

To one who knows the particulars of our science thoroughly, and who knows also what a variety of ideas have been resorted to in working out the whole body of truths of which the science is composed, there are few more impressive and elevating subjects of contemplation than the unity in the clear and bold outline of that noble structure.

I hope that you will not suppose, from my references to chemistry as promoting the development of these habits and powers of mind, that I wish to claim for that particular branch of science any exclusive merit of the kind; for I can assure you that nothing can be further from my intention.

I conceived that you would wish me to speak of that department of science which I have had occasion to study more particularly; but much that I have said of it might be said with equal truth of other studies, while some of its merits may be claimed in a higher degree by other branches of science. On the other hand, those highest lessons which I have illustrated by chemistry are best learnt by those whose intellectual horizon includes other provinces of knowledge.

Chemistry presents peculiar advantages for educational purposes in the combination of breadth and accuracy in the training which it affords; and I am inclined to think that in this respect it is at present unequalled. There is reason to believe that it will play an important part in general education, and render valuable services to it in conjunction with other scientific and with literary studies.

I trust that the facts which I have submitted to your consideration may suffice to show you how fallacious is that materialistic idea of physical science which represents it as leading away from the study of man's noblest faculties, and from a sympathy with his most elevated aspirations, towards mere inanimate matter. The material work of science is directed by ideas towards the attainment of further ideas. Each step in science is an addition to our ideas, or an improvement of them. A science is but a body of ideas respecting the order of nature.

Each idea which forms part of physical science has been derived from observation of nature, and has been tested again and again in the most various ways by reference to nature; but this very soundness of our materials enables us to raise upon the rock of truth a loftier structure of ideas than could be erected on any other foundation by the aid of uncertain materials.

The study of science is the study of man's most accurate and perfect intellectual labours; and he who would know the powers of the human mind must go to science for his materials.

Like other powers of the mind, the imagination is powerfully exercised, and at the same time disciplined, by scientific work. Every investigator has frequent occasion to call forth in his mind a distinct image of something in nature which could produce the appearances which he witnesses, or to frame a proposition embodying some observed relation; and in each case the image or the proposition is required to be true to the materials from which it is formed. There is perhaps no more perfect elementary illustration of the accurate and useful employment of the imagination than the process of forming in the language of symbols, from concrete data, one of those admirable general propositions called equations; on the other hand, the contemplation of the order and harmony of nature as disclosed to us by science supplies the imagination with materials of surpassing grandeur and brilliancy, while at the same time affording the widest scope for its effects.

The foregoing considerations respecting the meaning and use of scientific work will, I trust, afford us aid in considering what measures ought to be taken in order to promote its advancement, and what we can do to further the adoption of such measures.

Like any other natural phenomenon, the growth of knowledge in the human mind is favoured and promoted by certain circumstances, impeded or arrested by others; and it is for us to ascertain from experience what those circumstances respectively are, and how the favourable ones can be best combined to the exclusion of the others.

The best and noblest things in this world are the result of gradual growth by the free action of natural forces; and the proper function of legislation is to systematise the conditions most favourable to the free action which is desired.

I shall consider the words "Advancement of Science" as referring to the development and extension of our systematic knowledge of natural phenomena by investigation and research.

The first thing wanted for the work of advancing science is a supply of well qualified workers. The second thing is to place and keep them under the conditions most favourable to their efficient activity. The most suitable men must be found while still young, and trained to the work. Now I know only one really effectual way of finding the youths who are best endowed by nature for the purpose; and that is to systematise and develop the natural conditions which accidentally concur in particular cases, and enable youths to rise from the crowd.

The first of these is that a young man gets a desire for knowledge by seeing the value and beauty of some which he has acquired. When he has got this desire, he exerts himself to increase his store; and every difficulty surmounted increases his love of the pursuit, and strengthens his determination to go on. His exertions are seen by some more experienced man, who helps him to place himself under circumstances favourable to further progress. He then has opportunities of seeing original inquiries conducted, perhaps even of aiding in them; and he longs to prove that he also can work out new truths, and make some permanent addition to human knowledge. If his circumstances enable him to prosecute such work, and he succeeds in making some new observations worthy of publication, he is at once known by them to the community of scientific men, and employed among them.

We want, then, a system which shall give to the young favourable opportunities of acquiring a clear and, as far as it goes, a thorough knowledge of some few truths of nature such as they can understand and enjoy—which shall afford opportunity of further and further instruction to those who have best profited by that which has been given to them, and are anxious to obtain more—which shall enable the best students to see what original investigation is, and, if possible, to assist in carrying out some research—and, finally, which shall supply to each student who has the power and the will to conduct researches, all material conditions which are requisite for the purpose.

But investigators, once found, ought to be placed in the circumstances most favourable to their efficient activity.

The first and most fundamental condition for this is, that their desire for the acquisition of knowledge be kept alive and fostered. They must not merely retain the hold which they have acquired on the general body of their science; they ought to strengthen and extend that hold, by acquiring a more complete and accurate knowledge of its doctrines and methods; in a word, they ought to be more thorough students than during their state of preliminary training.

They must be able to live by their work, without diverting any of their energies to other pursuits; and they must feel security against want in the event of illness or old age.

They must be supplied with intelligent and trained assistants to aid in the conduct of their researches, and whatever buildings, apparatus, and materials may be required for conducting those researches effectively.

The desired system must therefore provide arrangements favourable to the maintenance and development of the true student-spirit in investigators while providing them with permanent means of subsistence, sufficient to enable them to feel secure and tranquil in working at science alone, yet not sufficient to neutralise their motives for exertion; and at the same time it must give them all external aids, in proportion to their wants and powers of making good use of them.

Now I propose to describe the outlines of such a system, framed for the sole purpose of promoting research, and then to consider what other results would follow from its working.

If it should appear possible to establish a system for the efficient advancement of science, which would be productive of direct good to the community in other important ways, I think you will agree with me that we ought to do all we can to promote its adoption.

Let the most intelligent and studious children from every primary school be sent, free of expense, to the most accessible secondary school for one year; let the best of these be selected and allowed to continue for a second year, and so on, until the *élite* of them have learnt all that is to be there learnt to advantage. Let the best pupils from the secondary schools be sent to a college of their own selection, and there subjected to a similar process of annual weeding; and, finally, let those who get satisfactorily to the end of a college curriculum be supplied with an allowance sufficient for their maintenance for a year, on condition of their devoting their undivided energies to research, under

the inspection of competent college authorities, while allowed such aids and facilities as the college can supply, with the addition of money-grants for special purposes. Let all who do well during this first year be allowed similar advantages for a second and even a third year.

Each young investigator thus trained must exert himself to obtain some appointment, which may enable him to do the most useful and creditable work of which he is capable, while combining the conditions most favourable to his own improvement.

Let there be in every college as many Professorships and Assistantships in each branch of science as are needed for the efficient conduct of the work there going on, and let every Professor and Assistant have such salary and such funds for apparatus, &c., as may enable him to devote all his powers to the duties of his post, under conditions favourable to the success of those duties; but let each professor receive also a proportion of the fees paid by his pupils, so that it may be his direct interest to do his work with the utmost attainable efficiency, and attract more pupils.

Let every college and school be governed by an independent body of men, striving to increase its usefulness and reputation, by sympathy with the labours of the working staff, by material aid to them when needed, and by getting the very best man they can, from their own or any other college, to supply each vacancy as it arises.

In addition to colleges, which are and always have been the chief institutions for the advancement of learning, establishments for the observation of special phenomena are frequently needed, and will doubtless be found desirable in aid of a general system for the advancement of science.

Now, if a system fulfilling the conditions which I have thus briefly sketched out were once properly established on a sufficient scale, it ought to develop and improve itself by the very process of its working; and it behoves us, in judging of the system, to consider how such development and improvement would come about.

The thing most needed at the present time for the advancement of science is a supply of teachers devoted to that object—men so earnestly striving for more knowledge and better knowledge as to be model students, stimulating and encouraging those around them by their example as much as by their teaching. Young men do not prepare themselves in any numbers for such a career:—

I. Because the chief influences which surround them at school and at college are not calculated to awaken in them a desire to obtain excellence of such kind.

II. Because they could not expect by means of such qualities to reach a position which would afford a competent subsistence.

Let these conditions be reversed, to the extent that existing teachers have powerful inducements to make their students love the study of science for its own sake, with just confidence that they will be able to earn a livelihood if they succeed in qualifying themselves to advance science, and the whole thing is changed. The first batch of young investigators will be dispersed among schools and colleges according to their powers and acquirements, and will improve their influence upon the pupils, and enable them to send up a second batch better trained than the first. This improvement will go on increasing, if the natural forces which promote it are allowed free play: and the youth of each successive generation will have better and more frequent opportunities of awakening to a love of learning, better help and guidance in their efforts to acquire and use the glorious inheritance of knowledge which had been left them, better and more numerous living examples of men devoting their whole lives to the extension of the domain of truth, and seeking their highest reward in the consciousness that their exertions have benefited their fellow-men, and are appreciated by them.

A young man who is duly qualified for the work of teaching the investigation of some particular branch of science, and who wishes to devote himself to it, will become a member of an association of men selected for their known devotion to learning, and for their ability to teach the methods of investigation in their respective subjects. Around this central group is ranged a frequently changing body of youths who trust to them for encouragement and guidance in their respective studies.

Our young investigator finds it necessary to study again more carefully many parts of his subject, and to examine accurately the evidence of various conclusions which he had formerly adopted, in order that he may be able to lead the minds of his pupils by easy and natural yet secure steps to the discovery of the general truths which are within their reach. He goes over his branch of science again and again from the foundation upwards striving each time to present its essential particulars more clearly and more forcibly, arranging them in the order best calculated to stimulate an inquiring mind to reflect upon their meaning, and to direct its efforts effectively to the discovery of the general ideas which are to be derived from them. He is encouraged in these efforts by the sympathy of his colleagues, and often aided by suggestions derived from their experience in teaching other branches of science, or by information respecting doctrines or methods which throw a light upon those of his own subject.

No known conditions are so well calculated to give a young investigator the closest and strongest grasp of his object of which he is capable as those in which he is placed while thus earnestly teaching it in a college; and inasmuch as a thorough mastery of known truths is needed by everyone who would work to advantage at the discovery of new truths of that kind, it will, in most cases, be an object of ambition to the ablest young investigators to get an opportunity of going through the work of teaching in a college, in order to improve themselves to the utmost for the work of original research. There is, however, another advantage to them in having such work to do; for the best way to ascertain at any one time what additions may be made to a science, is to examine the facts which have been discovered last, and to consider how far they confirm and extend the established ideas of the science, how far they militate against those ideas. An investigating teacher is constantly weaving new facts into the body of his science, and forming anticipations of new truths by considering the relation of these new facts to the old ones.

When our investigator has thus got a thorough mastery of his science and new ideas for its extension, he ought to have the opportunity of turning his improved powers to account by devoting more of his time to original research; in fact he ought to teach research by example more than hitherto, and less by elementary exercises upon known facts. If he has discharged the duties of his first post with manifest efficiency, he will be promoted, either in his own or some other college, to a chair affording more leisure and facility for original research by his own hands and by those of his assistants and pupils. Some investigators may find it desirable to give up after a while all teaching of previously published truths, and confine themselves to guiding the original researches of advanced pupils, while stimulating them by the example of their own discoveries. But most of them will probably prefer to do elementary teaching work from time to time, for the sake of the opportunity of going over the groundwork of their science, with a knowledge of the new facts and enlarged ideas recently established.

Now it must be observed that such a system as the above, once developed to its proper proportions, so as to send annually to secondary schools many thousands of poor children who would otherwise never enjoy such advantages, and so as to train to original investigation a corresponding proportion of them, would not only provide more young investigators than would be needed for systematic teaching functions, but would also give a partial training of the same kind to many whose abilities proved to be insufficient, or whose tastes were not congenial to such pursuit. Some would be tempted by an advantageous opening in an industrial pursuit or in the public service to break off their studies before completion, and others would find, after completing their training, a position of that kind more desirable or more attainable than a purely scientific appointment. Not only would much good of other kinds be accomplished by this circumstance, but we may say with confidence that the system could not work with full advantage for its own special purpose of promoting the advancement of science if it did not diffuse a knowledge of the truths and methods of science beyond the circle of teachers.

There is an urgent need of accurate scientific knowledge for the direction of manufacturing processes, and there could not be a greater mistake than to suppose that such knowledge need not go beyond the elementary truths of science. In every branch of manufacture improvements are made from time to time, by the introduction of new or modified processes which had been discovered by means of investigations as arduous as those conducted for purely scientific purposes, and involving as great powers and accomplishments on the part of those who conducted them.

Any manufacturer of the present day who does not make efficient arrangements for gradually perfecting and improving his

processes ought to make at once enough money to retire; for so many are moving onwards in this and other countries, that he would soon be left behind.

It would be well worth while to establish such a system of scientific education for the sake of training men to the habits of mind which are required for the improvement of the manufacturing arts; and I have no doubt that the expense of working the system would be repaid a hundred times over by the increase of wealth of the community; but I only mention this as a secondary advantage of national education.

A system of the kind could not expand to due dimensions, nor could it, once fully established, maintain itself in full activity, without intelligent sympathy from the community; and accordingly its more active-minded members must be taught some good examples of the processes and results of scientific inquiry, before they can be expected to take much interest in the results achieved by inquirers, and to do their share of the work requisite for the success of the system. I need hardly remind you that there are plenty of other strong reasons why some such knowledge of the truths of nature, and of the means by which they are found out, should be diffused as widely as possible throughout the community.

You perceive that in such educational system each teacher must trust to his own exertions for success and advancement; and he will do so if he is sure that his results will be known and compared impartially with those attained by others. Each governing body must duly maintain the efficiency of their school or college, if its support depend in some degree on the evidences of that efficiency; and they will try to improve their school if they know that every improvement will be seen and duly appreciated.

The keystone of the whole structure is the action of the State in distributing funds carefully among schools and colleges proportionally to the evidence of their doing good work, which could not be continued without such aid.

I am inclined to think that the State ought, as far as possible, to confine its educational grants to the purpose of maintaining and continuing good work which is actually being done, and rarely if ever to initiate educational experiments: first, because it is desirable to encourage private exertions and donations for the establishment of schools and colleges upon new systems, or in new localities, by giving the public full assurance that if any new institution establishes its right to existence, by doing good work for a while, it will not be allowed to die off for want of support; and, secondly, because the judicial impartiality required in the administration of public funds, on the basis of results of work, is hardly compatible with an advocacy of any particular means of attaining such results.

On the other hand, experience has shown that special endowments, which tie up funds in perpetuity for a definite purpose, commonly fail to attain their object under the altered circumstances which spring up in later generations, and not unfrequently detract from the efficiency of the institutions to which they are attached, by being used for objects other than those which it is their proper function to promote.

When there is felt to be a real want of any new institution for the promotion of learning, men are usually willing enough to devote time and money to the purpose of establishing it and giving it a fair trial. It is desirable that they should leave the State to judge of their experiment by its results, and to maintain it or not, according to the evidences of its usefulness. No institution ought, for its own sake, to have such permanent endowments as might deprive its members of motives for exertion.

The State could not, however, discharge these judicial functions without accurate and trustworthy evidence of the educational work done at the various schools and of its suceess. For this purpose a record must be kept by or under the direction of every teacher of the weekly progress of each pupil, showing what he has done and how he has done it. Official inspectors would have to see to these records being kept upon a uniform scale, so that their results might be comparable. The habit of keeping such records conduces powerfully to the efficiency of teachers; and, for the sake of the due development of the teaching system, it ought to prevail generally. Having such full and accurate means of knowing what opportunities of improvement pupils have enjoyed, and what use they have made of those opportunities, Government ought to stimulate their exertions and test their progress by periodical examinations. It is of the utmost importance to allow any new and improved system of instruction to develop itself freely, by the exertions of those who are willing to undertake the labour and risk of trying it on a practical scale; and the pupils who acquire upon such new system a command of any branch of science, ought to have a fair opportunity of showing what they have achieved and how they have achieved it. An able and impartial examiner, knowing the new systems in use, will encourage each candidate to work out his results in the manner in which he has been taught to work out results of the kind.

Examinations thus impartially conducted with a view of testing the success of teachers in the work which they are endeavouring to do, have a far higher value, and consequent authority, than those which are conducted in ignorance or disregard of the process of training to which the candidates have been subjected; and we may safely say that the examination system will not attain its full usefulness until it is thus worked in intimate connection with a system of teaching.

In order to give every one employed in the educational system the utmost interest in maintaining and increasing his efficiency, it is essential that a due measure of publicity be given to the chief results of their respective labours. Schools and colleges ought, to a considerable extent, to be supported by the fees paid by pupils for the instruction received; and every Professor being in part dependent upon the fees of his pupils will have a direct interest in attracting more pupils to his classes or laboratories. The fame of important original investigations of his own or his pupils, published in the scientific journals, is one of the natural means by which a distinguished Professor attracts disciples, and the success of his pupils in after life is another His prospects of promotion will depend mainly on the opinion formed of his powers from such materials as these by the governing bodies of colleges and by the public; for if each college is dependent for success upon the efficiency of its teaching staff, its governing body must do their best to fill up every vacancy as it arises by the appointment of the ablest and most successful Professor whom they can get; and any college which does not succeed in obtaining the services of able men will soon lose reputation, and fall off in numbers.

There are, however, further advantages to the working of the system to be derived from full publicity of all its more important proceedings. It will supply materials for the formation of a sound public opinion respecting the proceedings of the authorities in their various spheres of action. A claim for money might be made upon Government by the rulers of some college upon inadequate grounds; or a just and proper claim of the kind might be disregarded by Government. Neither of these things will be likely to happen very often if the applications, together with the evidence bearing on them, are open to public scrutiny and criticism; and when they do occasionally happen, there will be a natural remedy for them.

If I have succeeded in making clear to you the leading principles of the plan to be adopted for the advancement of science, including, as it necessarily must do, national education generally, you will, I think, agree with me that, from the very magnitude and variety of the interests involved in its action, such system must of necessity be under the supreme control of Government. Science will never take its proper place among the chief elements of national greatness and advancement until it is acknowledged as such by that embodiment of the national will which we call the Government. Nor can the various institutions for its advancement develop duly their usefulness until the chaos in which they are now plunged gives place to such order as it is the proper function of Government to establish and maintain.

But government has already taken, and is continuing to take action in various matters affecting elementary popular education and higher scientific education, and it would be difficult to arrest such action, even if it were thought desirable to do so. The only practical question to be considered is how the action of Government can be systematised so as to give free play to the natural forces which have to do the work.

By establishing official examinations for appointments and for degrees Government exerts a powerful influence on the teaching in schools and colleges, without taking cognizance, except in some few cases, of the systems of teaching which prevail in them. Again, they give grants of public money from time to time in aid of colleges or universities, or for the establishment of a high school under their own auspices. Sometimes they endow a Professorship. In taking each measure of the kind they are doubtless influenced by evidence that it is in itself a good thing,

calculated to promote the advancement of learning. But a thing which is good in itself may produce evil effects in relation to others, or good effects incommensurate with its cost. Thus examinations afford most valuable aid to educational work when carried on in conjunction with earnest teachers; yet when established in the absence of a good system of education, they are liable to give rise to a one-sided training contrived with a special view of getting young men through the examinations. If no properly educated young men were found for a particular department of the public service, and an examination of all candidates for such appointments were to be established for the purpose of improving the system of training, candidates would consider their power of answering such questions as appeared likely to be set as the condition of their obtaining the appointments, and they would look out for men able and willing to train them to that particular work in as direct and effective a manner as possible. The demand for such instruction would soon be supplied. Some teachers would undertake to give instruction for the mere purpose of enabling candidates to get through the examination; and by the continued habit of such work would gradually come to look upon the examiners as malignant beings who keep youths out of office, and whose vigilance ought to be evaded by such means as experience might show to be most effective for the purpose. Once this kind of direct examination-teaching has taken root, and is known to produce the desired effect of getting young men through the examinations, its existence encourages the tendency on the part of the candidates to look merely to the examination as the end and aim of their study; and a class of teachers is developed whose exertions are essentially antagonistic to those of the examiners.

There are, no doubt, teachers with a sufficiently clear apprehension of their duty, and sufficient authority, to convince some of the candidates that the proper object of their study should be to increase their power of usefulness in the career for which they are preparing themselves, by thoroughly mastering up to a prescribed point certain branches of knowledge; and that until they had honestly taken the means to do this and believed they had done it effectually, they ought not to go up for examination nor to wish to commence their career.

But it is desirable that all teachers be placed in such circumstances that it may become their interest as well as their duty to co-operate to the utmost of their powers in the object for which the examiners are working. For this purpose their records of the work done under their guidance by each pupil ought to be carefully inspected by the examiners before framing their questions, and ought to be accepted as affording the chief evidence of the respective merits of the pupils.

This is not the place for considering how the general funds for an effective system of national education can best be raised, nor how existing educational endowments can best be used in aid of those funds. It is well known that some colleges of Oxford and Cambridge are possessed of rich endowments, and that many distinguished members of those universities are desirous that the annual proceeds of those endowments should be distributed upon some system better calculated to promote the advancement of learning than that which generally prevails. Indeed we may confidently hope that, true to their glorious traditions, those colleges will be led, by the high-minded and enlightened counsels of their members, to rely upon improving usefulness in the advancement of learning as the only secure and worthy basis of their action in the use of their funds, so that they may take a leading part in such system of national education as may be moulded out of the present chaos.

But the foundations of a national system of education ought to be laid independently of the present arrangements at Oxford and Cambridge, for we may be sure that the more progress the system makes the more easy will become the necessary reforms in the older universities and colleges.

It is clearly undesirable that Government should longer delay obtaining such full and accurate knowledge of the existing national resources for educational purposes, and of the manner in which they are respectively utilised, as may enable them to judge of the comparative prospects of usefulness presented by the various modes of distributing educational grants. They ought to know what has been done and what is doing in the various public educational establishments before they can judge which of them would be likely to make the best use of a grant of public money.

We have official authority for expecting such impartial administration of educational grants; and it cannot be doubted that, before long, due means will be taken to supply the preliminary conditions.

You are no doubt aware that a Royal Commission was appointed some time ago in consequence of representations made to Government by the British Association on this subject, and it is understood that their instructions are so framed as to direct their particular attention to the manner in which Government may distribute educational grants. The Commission is moreover composed of most distinguished men, and we have every reason to anticipate from their labours a result worthy of the nation and of the momentous occasion.

In speaking of public educational establishments, I refer to those which by their constitution are devoted to the advancement of learning without pecuniary profit to their respective governing bodies. The annual expenditure requisite for keeping up a national system of popular education will necessarily be considerable from the first, and will become greater from year to year; but once Englishmen are fully alive to the parhmount importance of the subject, and see that its attainment is within their reach, we may be sure that its expense will be no impediment. England woul not deserve to reap the glorious fruits of the harvest of knowledge if she grudged the necessary outlay for seed and tillage, were it even ten times greater than it will be. It is no use attempting to establish a national system on any other than a truly national basis. Private and corporate funds inevitably get diverted from popular use, after a few generations, to the use of the influential and rich. A national system must steadily keep in view the improvement of the poor, and distribute public funds each year in the manner best calculated to give to the youths of the poorest classes full opportunities of improvement proportional to their capacities, so that they may qualify themselves for the utmost usefulness to their country of which they are capable. The best possible security for the proper administration of the system will be found in the full and speedy publicity of all the particulars of its working.

It has been frequently remarked that a great proportion of English investigators are men of independent means, who not only seek no advancement as a reward of their labours, but often sacrifice those opportunities of improving their worldly position which their abilities and influence open up to them, for the sake of quietly advancing human knowledge. Rich and powerful men have very great temptations to turn away from science, so that those who devote their time and money to its service prove to us how true and pure a love of science exists in this country, and how Englshmen will cultivate it when it is in their power to do so.

Now and then a youth from the poorer classes is enabled by fortunate accidents and by the aid of a friendly hand to climb to a position of scientific activity, and to give us, as Faraday did, a sample of the intellectual powers which lie fallow in the great mass of the people.

Now, the practical conclusion to which I want to lead you is that it rests with you, who represent the national desire for the advancement of science, to take the onlo measures which can now be taken towards the establishment of a system of education worthy of this country, and adapted to the requirements of science. In the present stage of the business the first thing to be done is to arouse public attention by all practicable means to the importance of the want, and to get people gradually to agree to some definite and practicable plan of action. You will, I think, find that the best way to promote such agreement is to make people consider the natural forces which have to be systematised by legislation, with a view of enabling them to work freely for the desired purpose. When the conditions essential to any national system come to be duly appreciated by those interested in the cause of education, means will soon be found to carry out the necessary legislative enactments.

The highest offices in the State are on our present system filled by men who, whatever their political opinions and party ties, almost infallibly agree in their disinterested desire to signalise their respective terms of office by doing any good in their power. Convince them that a measure desired by the leaders of public opinion is in itself good and useful, and you are sure to carry it.

And, on the other hand, England is not wanting in men both able and willing to come forward as the champions of any great cause, and to devote their best powers to its service.

I may well say this at Bradford after the results achieved by your Member in the Elementary Education Act.

Objections will of course be raised to any system on the score of difficulty and expense, more especially to a complete and

good system. Difficult of realisation it certainly must be, for it will need the devoted and indefatigable exertions of many an able and high-minded man for many a long year. Only show how such exertions can be made to produce great and abiding results, and they will not be wanting. And as for expense, you will surely agree with me that the more money is distributed in such frugal and effective manner, the better for the real greatness of our country.

What nobler privilege is attached to the possession of money than that of doing good to our fellow men? and who would grudge giving freely from his surplus, or even depriving himself of some comforts, for the sake of preparing the rising generation for a life of the utmost usefulness and consequent happiness?

I confidently trust that the time will come when the chief item in the annual budget of the Chancellor of the Exchequer will be the vote for National Education; and when in some later age our nation shall have passed away, when a more true civilisation has grown up and has formed new centres for its throbbing life, when there are but broken arches to tell of our bridges and crumbling ruins to mark the sites of our great cathedrals—then will the greatest and noblest of England's works stand more perfect and more beautiful than ever; then will some man survey the results of Old England's labours in the discovery of imperishable truths and laws of nature, and see that her energy and wealth were accompanied by some nobler attributes—that while Englishmen were strong and ambitious enough to grasp power, they were true enough to use it for its only worthy purpose—that of doing good to others.

I must not, however, trespass longer upon your time and your kind attention. My subject would carry me on, yet I must stop without having done half justice to it.

If I have succeeded in convincing you that a National system of Education is now necessary and possible, and in persuading you to do what you respectively can to prepare the way for it, I shall feel that the first step is made towards that great result.

Sectional Proceedings

SECTION B.—Chemical Science.

Address of the President, W. J. Russell, F.R.S.

Of late years it has been the custom of my predecessors in this chair to open the business of the section with an address, and the subject of this address has almost invariably been a review of the progress of chemistry during the past year. I purpose, with your leave, to-day to deviate somewhat from this precedent, and to limit my remarks, as far as the progress of chemistry is concerned, to the history of one chemical substance. The interest and the use of an annual survey, at these meetings, of the progress of chemistry, has to a certain extent passed away, for the admirable extracts of all important chemical papers, now published by the Chemical Society, has in a great measure taken its place, and offers to the chemical student a much more thorough means of learning what progress his science is making than could possibly be done by the study of a presidential address. Doubtless these abstracts of chemical papers are known to others than professional chemists, but I cannot pass them over without recording the great use they have proved to be, how much they have done already in extending in this country an exact knowledge of the progress of science on the continent, and in helping and in stimulating those who are engaged in scientific pursuits in this country. I believe few grants made by this Association have done more real good than those which have enabled the Chemical Society to publish these abstracts.

I dwell for a moment on the doings of the Chemical Society, for I believe in the progress of this Society we have a most important indication of the progress of chemical science in this country. The number of original papers communicated to the Society during the past year has far exceeded that of previous years: during last year fifty-eight papers were read to the Society, whereas the average number for the last three years is only twenty-nine. Further, I may say, there is every appearance of this increased activity not only continuing, but even increasing. Another matter connected with the Society deserves a passing word, I mean its removal from its old rooms at Burlington House, which afforded it very insufficient accommodation, to its new ones in the same building. This transference which is now taking place, will give to the Society a great increase of accommodation, and thus admit of larger audiences attending the lectures, of the proper development of the library, and of the full illustration by experiment of the communications made to it. These improvements must act most beneficially on the Society, and stimulate its future development; even now it numbers some 700 members, and certainly is not one of the least active or least useful of the many scientific societies in London. Since our last meeting, at Brighton, we have lost the most renowned of modern chemists—Liebig. His influence on chemistry through a long and most active life has yet to be written. Publishing his first paper fifty years ago, it is difficult for chemists of the present day to realise the changes in chemical thought, in chemical knowledge, and in chemical experiments which he lived through, and was more than any other chemist active in promoting. His activity was unwearied: he communicated no less than 317 papers to different scientific journals, and almost every branch of chemistry received some impetus from his hand.

Liebig took an active interest in this Association, and I believe the last paper he wrote was one in answer to a communication made at the last meeting of this Association. On two occasions he attended the meetings of the British Association, and has communicated many papers to this section. The meeting at Liverpool in 1837 was the first at which he was present; he there communicated to this section a paper on the products of the decomposition of uric acid, and further gave an account of his most important discovery, made in conjunction with Wöhler, of the artificial formation of urea. At this meeting Liebig was requested to prepare a report on the state of our knowledge of isomeric bodies. This request, although often repeated, was never complied with. He was also requested to report on the state of organic chemistry and organic analysis—thus our section was evidently desirous of giving him full occupation. At the meeting in 1840 at Glasgow, a paper on "Poisons, Contagions, and Miasms," by Liebig was read; it was in fact an abstract of the last chapter in his book on "Chemistry in its applications to Agriculture and Physiology," and the work itself appeared about the same time, dedicated to this Association. Liebig says:—"At one of the meetings of the Chemical Section of the British Association for the advancement of Science, the honourable task of preparing a report upon the state of Organic Chemistry was imposed upon me. In this present work I present the Association with a part of this report." At the next meeting, which was held at Plymouth, in 1841, there was an interesting letter from Liebig to Dr. Playfair read to our section; in it, among other matters, Liebig describes an "excellent method" devised by Drs. Will and Varrentrapp for determining the amount of nitrogen in organic bodies; he also says we have repeated all the expressions of Dr. Brown on the production of silicon from paracyanogen, but we have not been able to confirm one of his results; what our experiences prove is that paracyanogen is decomposed by a strong heat into nitrogen gas, and a residue of carbon which is exceedingly difficult of combustion.

To the next meeting—it was at Manchester, and Dalton was the president of this section—Dr. Playfair communicated an abstract of Professor Liebig's report "On Organic Chemistry applied to Physiology and Pathology." This abstract is printed in our proceedings, and the complete work is looked upon as the second part of the report on Organic Chemistry. This Association may therefore fairly consider that it exercised some influence on Liebig in the production of the most important works that he wrote. Playfair's abstract must have been listened to with the greatest interest, and I doubt not the statements made sharply criticised, specially by the physiologists then at Manchester. Playfair concludes his abstract with these words, thus summing up the special objects of these reports:—"In the opinion of all, Liebig may be considered a benefactor to his species, for the interesting discoveries in agriculture, published by him in the first part of his report. And having in that pointed out means by which the food of the human race may be increased, in the work now before us he follows up the chain in its continuation, and shows how that food may be best adapted to the nutrition of man. Surely there are no two subjects more fitted than these for the contemplation of the philosopher; and by the consummate sagacity with which Liebig has applied to their elucidation the powers of his mind, we are compelled to admit that there is no living philosopher to whom the Chemical Section could have more appropriately entrusted their investigation."

At the meeting at Glasgow, in 1855, Liebig was also present, but then only communicated to this section a short paper on ful-

minuric acid, and some remarks on the use of lime water in the manufacture of bread. Such I believe is the history of the direct relationship which has existed between Liebig and this Association. Indirectly we can hardly recognise how much we owe to him. Interested as he was in the work of this Association I could not but to-day record the instances of direct aid and support which this section has received from him.

I pass on now to the special subject to which I wish to ask your attention.

It is the history of the vegetable colouring matter found in madder. It has been in use from time immemorial, and is still one of the commonest and most important of dyes. It is obtained from a plant largely cultivated in many parts of the world for the sake of the colour it yields, and the special interest which now attaches to it is, that the chemist has lately shown how this natural colouring matter can be made in the laboratory as well as in the fields; how by using a bye-product, which formerly was without value, thousands of acres can be liberated for the cultivation of other crops, and the colouring matter which they formerly produced be cheaper and better prepared in the laboratory or in the manufactory. That a certain colouring matter could be obtained from the roots of the *Rubia tinctorum*, and other species of the same plant, has been so long known, that apparently no record of its discovery remains.

Pliny and Dioscorides evidently allude to it. The former, referring to its value as a dyeing material, says, "It is a plant little known except to the sordid and avaricious, and this because of the large profits obtained from it, owing to its employment in dyeing wool and leather." He further says, "The madder of Italy is the most esteemed, and especially that grown in the neighbourhood of Rome, where and in other places it is produced in great abundance." He further describes it as being grown among the olive-trees, or in fields devoted especially to its growth. The madder of Ravenna, according to Dioscorides, was the most esteemed. Its cultivation in Italy has been continued till the present time, and in 1863 the Neapolitan provinces alone exported it to the value of more than a quarter of a million sterling. At the present day we are all very familiar with this colouring matter as the commonest that is applied to calicoes. It is capable of yielding many colours, such as red, pink, purple, chocolate, and black. The plant in which is the source of this colouring matter is nearly allied botanically and in appearance to the ordinary Galiums, or bed-straws. It is a native probably of Southern Europe as well as Asia. It is a perennial with herbaceous stem, which dies down every year; its square-jointed stalk creeps along the ground to a considerable distance, and the stem and leaves are rough with sharp prickles. The root, which is cylindrical, fleshy, and of a pale yellow colour, extends downwards to a considerable depth. It is from this root, which, when dried, is known as madder, that the colouring matter is obtained. The plant is propagated from suckers or shoots. These require some two or three years to come to full maturity and yield the finest colours, although in France the crop is often gathered after only eighteen months' growth. From its taking so long to develop, it is evidently a crop not adapted to any ordinary series of rotation of crops. The plant thrives best in a warm climate, but has been grown in this country and in the north of Europe.

In India it has been grown from the earliest times, and, as before stated, has been abundantly cultivated in Italy, certainly since the time of Pliny; he also mentions its cultivation in Galilee. In this country its culture has often been attempted, and has been carried on for a short time, but never with permanent success. The madder now used in England is imported from France, Italy, Holland, South Germany, Turkey, and India. In 1857 the total amount imported into this country was 434,056 cwts., having an estimated value of 1,284,989*l*., and the average annual amount imported during the last seventeen years is 310,042 cwts.; while the amount imported last year, 1872, was 283,274 cwts., valued at 922,244*l*. In 1861, it was estimated that in the South Lancashire district alone, 150 tons of madder were used weekly, exclusive of that required for preparing garancine. I quote these figures as showing the magnitude of the industry that we are dealing with. Another point of much interest is the amount of land required for the cultivation of this plant. In England it was found that an acre yielded only from 10 to 20 cwt. of the dried roots, but in South Germany and in France the same amount of land yields about twice that quantity. The madder cultivator digs up the roots in autumn, dries them, in some cases peels them, by beating them with a flail, and exports them in the form of powder, whole root, or, after treatment with sulphuric acid, when it is known as garancine.

The quality of the root varies much, that from the Levant, known as Turkey root, is most valued. According, however, to the colour to be produced, is the madder from one source or another preferred.

To obtain the colouring matter, which is but very slightly soluble in water, from these roots, they are mixed, after being ground, with water in the dye-vessel, and sometimes a little chalk is added. The fabric to be dyed is introduced, and the whole slowly heated; the colouring matter gradually passes from the root to the water, and from the water to the mordanted fabric, giving to it a colour dependent of course on the nature of the mordant.

To trace the chemical history of this colouring matter, we have to go back to the year 1790, when a chemist of the name of Watt precipitated the colouring matter of madder by alum from neutral, alkaline, and acid solutions: he obtained two different colouring matters, but could not isolate them, and many different shades of colours. Charles Batholdi asserted that madder contained much magnesic sulphate, and Hautmann observed the good effect produced on madder by the addition of calcic carbonate. In 1823, F. Kuhlmann made evidently a careful analysis of the madder-root, and describes a red and a fawn colouring matter; but the first really important advance made in our knowledge of the chemical constitution of this colouring matter was by Colin and Robiquet in 1827. They obtained what they believed to be, and what has since really proved to be, the true colouring principle of madder, and obtained it in a state of tolerable purity. Their process for preparing it was very simple. They took Alsace madder in powder, digested it with water, obtaining thus a gelatinous mass, which they treated with boiling alcohol, then evaporated off four-fifths of the alcohol, and treated the residue with a little sulphuric acid, to diminish its solubility. Then, after washing it with several litres of water, they got a yellowish substance remaining. Lastly, they found that on moderately heating this product in a glass tube, they obtained a yellowish vapour formed of brilliant particles, which condensed, giving a distinct zone of brilliant needles, reflecting a colour similar to that from the native lead chromate. They named this substance alizarine, from the Levant name for madder, Alizari, the name by which it is still known there.

A few years later we find other chemists attacking this same subject; in 1831 Gaultier de Claubry and J. Persoz published the account of a long research on the subject; they described two colouring matters, a red and a rose one—the red one was alizarine and the rose one was another body nearly allied to it, and now well known as purpurine. Runge also made an elaborate examination of the madder root; he found no less than five different colouring matters in it—madder-red, madder-purple, madder-orange, madder-yellow, and madder-brown. The first three he considers to be suited for dyeing purposes, but not the last two.

Runge's madder-red is essentially impure alizarin, and his madder-purple impure purpurine. He does not give any analysis of these substances. During the next ten years this subject seems to have attracted but little attention from chemists, but in 1846 Shiel prepared the madder-red and madder-purple of Runge, by processes very similar to those employed by Runge, and analysed these substances. For madder-red he gives the formula $C_{28}H_{18}O_9$, which differs only by H_2O from the formula now adopted. For the madder-purple he gives the formula $C_{28}H_{20}O_{15}$, and for the same substance, after being sublimed, $C_7H_8O_4$. The chemist who has worked most on this subject, and to whom we are principally indebted for what we know with regard to the different constituents contained in the madder root, is Dr. Schunk of Manchester. In Liebig's Annalen for 1848 he gives a long and interesting account of his examination of madder; he isolated and identified several new substances which are most important constituents of the root, and has since this time added much to our knowledge of the chemical constitution of madder. In the paper above alluded to he confirms the presence of the alizarine, and gives to it the formula $C_{14}H_{10}O_4$. The principal properties of this body may best be sketched here. Its volatility and brilliant crystalline appearance have already been mentioned; it is but slightly soluble in cold water, but much more so in alcohol, in ether, and in boiling-water. The colour of its solution is yellow, and when it separates out from a liquid it has a yellow flocculent appearance, differing thus greatly from the red brilliant crystalline substance before described. In order to

obtain this latter body heat had always been used, so until the elaborate experiments of Schunk it was a question whether the heat did not produce a radical change in the substance, whether, in a word, these two bodies were really identical. Schunk's experiments proved that they were, and consequently that this beautiful colouring matter alizarine existed as such in madder. If, however, we go one step further back and examine the fresh root of *Rubia tinctorum*, that is, as soon as it is drawn from the ground, for some time we shall find no trace of alizarine there. On slicing the root it is seen to be of a light carroty colour, and an almost colourless liquid can be squeezed out of it, but this is entirely free from the colouring matters of madder. Let the roots, however, be kept if only for a short time, and then they will give abundant evidence of the presence of alizarine; if simply heated alizarin may be volatilised from them. It appears then that the whole of the tinctorial power of this root is developed after the death of the plant. Schunk explains this curious phenomenon as follows:—That in the cells of the living plant there is a substance which he has isolated, and has named rubian; it is easily soluble in water and in alcohol; the solution is of a yellow colour, and has an intensely bitter taste; when dry it is a hard, brown, gum-like body. It has none of the properties of a dye stuff, but if we take a solution of it, add some sulphuric or hydrochloric acid to it, and boil, a yellow flocculent substance will slowly separate out, and on filtering it off and washing it, it will be found to have the tinctorial properties of madder and to contain alizarine. In the liquid filtered from it there is, with the acid added, an uncrystallisable sugar, so that in this way the original product in the root, the rubian, has apparently been split up into alizarine and into sugar. To apply this reaction to what goes on in the root after its removal from the ground, we have to find if any other substances can take the place of the boiling dilute acid, and Schunk has shown there exists in the root itself a substance which is eminently fitted to produce this splitting up of the rubian. He obtained this decomposing agent from madder simply by digesting it in cold water, and then adding alcohol to the liquid; this threw down a reddish flocculent substance, and if only a small portion of this be added to an aqueous solution of rubian and allowed to stand for a few hours in a warm place, it was found that the rubian was gone, and in place of it there was a thick tenaceous jelly; this, treated with cold water, gave to it no colour, no bitter taste, but much sugar. From the jelly, remaining insoluble, alizarine could be extracted. In fact, of all known substances this very one found in the madder itself is best suited for effecting this decomposition of the rubian.

It appears, then, that these two bodies must exist in the root. The history then seems complete. The two substances are kept apart during the life of the plant in some way of which we know nothing, but as soon as it dies they begin slowly to act on one another, developing thus the colouring matters in madder. It has long been known to dyers that the amount of colouring matter in madder will increase on keeping it; even for years it will go on improving in quality, and an experiment of Schunk's shows that the ordinary madder as used by the dyer has not all the rubian converted into colouring matter, for on taking a sample of it and extracting it with cold water he got an acid solution devoid of dyeing properties, but on allowing this solution to stand some time it gelatinised and then possessed dyeing properties.

Coincident with the appearance of Schunk's first paper was one by Debus on the same subject. He looked upon alizarine as a true acid, and gave it the name of Lizaric acid, but as far as the composition of it was concerned the percentage which he obtained agreed closely with those given by Schunk. One other investigation concludes all that is important in the history of alzarine as obtained from madder. This last research is of great interest; it was by Julius Wolff and Adolph Strecker, and published in 1850. They confirm the results of others so far that there are in the madder root two distinct colouring substances—this important one alizarin, and the other one purpurine. They prepare these colouring matters much in the same way that Schunk did, and very carefully purify and analyse them; the formulæ which they give for them differ, however, from Schunk's: for alizarine they give the formula $C_{20}H_{12}O_6$ and for purpurine $C_{18}H_{12}O_6$. Further, they suggest that by the process of fermentation the former is converted into the latter, and they show that by oxidation they both yielded phthalic acid. Since the publication of this research, until the last year or two, this formula for alizarine has been generally adopted by chemists, and in most modern books we find it given as expressing the true composition of that body. It was not only the careful and elaborate work which they devoted to the subject, but also the ingenious and apparently well-founded theory on the subject which carried conviction with it. Laurent had shown, not many years before, that when naphthalin, that beautiful white crystalline substance obtained from coal tar, was acted on by chlorine, and then treated with nitric acid, a body known as chlornaphthalic acid and having the composition $C_{20}H_{10}Cl_2O_6$ was obtained, and on comparing this formula with the one they had obtained for alizarine, Wolff and Strecker at once concluded that it really was alizarine, only containing two atoms of chlorine in place of two of hydrogen; make this replacement, an operation generally easily performed, and from naphthalin, they had prepared alizarine. Further, this relationship between chlornaphthalic acid, and alizarine is borne out in many ways; it, like alizarine, has the power of combining with different basic substances, has a yellow colour, is insoluble in water, melts at about the same temperature, is volatile, and when acted on by alkalis gives strongly coloured solutions. Taking then all these facts into consideration, can we wonder that these chemists feel convinced that they have established the composition of alizarine, and have shown the source from which it is to be obtained artificially? Apparently but one very simple step remains to crown their work with success, that of replacing the chlorine by hydrogen. Melsens had only shortly before shown how this substitution could easily be made in the case of choracetic acid by acting on it with potassium amalgam, and Kolbe had used the battery for the same purpose. Both these processes, and doubtless all others that the authors can think of, are tried upon the chloronaphthalic acid, but chloronaphthalic acid it remains, and they are obliged to confess they are unable to make this substitution. Still they are strong in the belief that it is to be done and will be done, and conclude the account of their researches by pointing out the great technical advantage it will be to get alizarine from a worthless substance such as naphthalin. One cannot help even now sympathising with these chemists in their not being able to confirm what they had really the strongest evidence for believing must prove to be a great discovery. We now know, however, that had they succeeded in effecting this substitution, or had they in any other way obtained this chloronaphthalic acid without the chlorine, if I may so speak of it, which since their time has been done by Martius and Griess, alizarine would not have been obtained, but a body having a remarkable parallelism in properties to it would have been. This body, like alizarine, is of a yellowish colour, but slightly soluble in water, easily in alcohol and in ether, is volatile, and on oxidation yields the same products, it is, in fact, an analogous body, but belonging to another group. We also know that the formula proposed by Wolff and Strecker, and so long in use, is not the correct one. But little more remains to be added with regard to the history of alizarine as gathered from the study of the natural substance. Schutzenberger and Paraf suggested doubling Wolff and Strecker's formula for alizarine, and Bolley suggested the formula $C_{20}H_{13}O_6$, which owing to the uneven number of hydrogen atoms was soon rejected. If we compare our present knowledge of alizarine with what it was when these researches on the natural product were completed, it is as lightness compared to darkness, and we may well ask whence has come this influx of knowledge? the answer I hope to show you is undoubtedly that it has come from the careful and accurate study of abstract chemistry. I know of no history in the whole of chemistry which more strikingly illustrates how the prosecution of abstract science lays the foundation for great practical improvements. My object now, is then to show you, as shortly as I can, how by indirect means the composition of alizarine was discovered, how it has been built up artificially, and how it is superseding for manufacturing purposes the long-used natural product.

To trace this history from its source we must go back to 1785, when an apothecary of the name of Hofmann obtained the calcium salt of an acid called quinic acid from cinchona bark. This acid is now known to be of common occurrence in plants, it exists in the bilberry and in coffee, in holly, ivy, oak, elm, and ash leaves, and probably many others. Liebig also prepared the calcium salt, and was the first to give a complete analysis of it; the formula he gave for it was $C_{15}H_{24}O_{12}$. Bauss on repeating Liebig's experiments arrived at a somewhat different conclusion, and gave the formula $C_{15}H_{20}O_{10}$. In 1835 at Liebig's suggestion, to determine which formula was correct, Alexander Woskrensky, from St. Petersburg, then a

student at Giessen, undertook the further investigation of this subject, and established the formula $C_{14}H_{24}O_{12}$ the one in fact now in use. In the course of this investigation, which he carried further than merely settling the percentage composition of this acid, he describes what to us now is of most interest, a new substance having peculiar and very marked properties. He says that when a salt of quinic acid is burnt at a gentle heat he gets aqueous vapour, the vapour of formic acid, and a deposit of golden needles which are easily sublimed. Afterwards he describes how this same golden substance may be obtained from any salt of quinic acid by heating it with manganic dioxide and dilute sulphuric acid; it then distils over, condensing in golden yellow needles on the sides of the receiver, and may be rendered pure by resublimation. The composition of this body he finds to be C_3H_2O, and names it quinoyl, a name strongly objected to by Benzelius, as conveying a wrong impression of the nature of the body; he proposes in place of it the name quinone, by which it is still known. Far as this body would seem to be removed from alzarine, yet is the study of its properties which led to the artificial production of alizarine.

Some years afterwards Wöhler also explained them by the decomposition of quinic acid; he prepares again this quinone and follows exactly the process described by Woskrensky. He states that with regard to the properties of this remarkable body he has nothing particular to add. However, he proposes a different formula for it, and discovers and describes other bodies allied to it. Among these is Hydroquinone $C_6H_6O_2$. Laurent afterwards shows that the formula proposed by Wöhler is inconsistent with his and Gerhard's views, and by experiment confirms the former formula for this body. Although many other chemists devoted much attention to this substance, still its real constitution and relation to other compounds remained unknown.

Thus Wöhler, Laurent, Hofmann, Städler, and Hesse, all had worked at it, and much experimental knowledge with regard to it had been acquired. One important point in its history was first the discovery of chloranil by Erdmann in 1841, and then Hofmann, showing that by heating quinone with potassic chlorate and hydrochloric acid chloranil could be obtained from it; that, in fact, chloranil was quinone in which all the hydrogen had been replaced by chlorine. Perhaps the most general impression among chemists was that in constitution it was a kind of aldehyde, certainly its definite place among chemical compounds was unknown.

Kekulé suggests a rational formula for it, but it is to Carl Graebe that we owe our knowledge of its true constitution. In 1868 he published a remarkable and very able paper on the quinone group of compounds, and then first brought forward the view that quinone was a substitution derivative of the hydrocarbon benzol (C_6H_6). On comparing the compounds of these two bodies it is seen that the quinone contains two atoms of oxygen more and two atoms of hydrogen less than benzol, and Graebe, from the study of the decomposition of the quinone, and from the compounds it forms, suggested that the two atoms of oxygen form in themselves a group which is divalent, and thus replace the two atoms of hydrogen. This supposition he very forcibly advocates and shows its simple and satisfactiory application to all the then known reactions of this body. This suggestion really proved to be the key, not only to the explanation of the natural constitution of quinone and its derivatives, but to much important discovery besides. At this time quinone seemed to stand alone, no other similarly constituted body was known to exist; but what strikingly confirms the correctness of Graebe's views, and indicates their great value, is that immediately he is able to apply his lately gained knowledge, and to show how other really analogous bodies, other quinones in fact, already exist. He studied with great care this quinone series of compounds and the relation they bore to one another, the relation the hydrocarbon, benzole, bore to its oxidised derivative, quinone, and its relation to the chlorine substitution products derivable from it. At once this seems to have led Graebe to the conclusion, that another such series already existed ready formed, and that its members were well known to chemists, that in fact naphthalin ($C_{10}H_8$) was the parent hydrocarbon and that the chloroxynaphthalin chloride ($C_{10}H_4Cl_2O_2$) and the perchloroxynaphthalin chloride ($C_{10}Cl_6O_2$) were really chlorine substitution compounds of the quinone of this series, corresponding to the bichloroquinone and to chloranil. That the chloroxynaphthalic acid $C_{10}H_4Cl(HO)O_2$ and the perchloroxynaphthalic acid $C_{10}Cl_5(HO)O_2$, all compounds previously discovered by Laurent, were really bodies belonging to that series, and further the supposed isomeric of alizarin discovered by Martius and Griess was really related to this last compound, having the composition $C_{10}H_5(HO)O_2$. Further he was able to confirm this by obtaining the quinone itself of this series, the body having the formula $C_{10}H_6(O_2)$ containing also two atoms less of hydrogen, and two atoms more of oxygen than the hydrocarbon naphthalin, and to the body he gave the characteristic name of naphthoquinone. The chlorine compounds just named are thus chloro-naphthoquinone, or chloroxynaphthoquinone, and correspond to the former chloroquinones, Martius and Griess compound will be an oxynaphthoquinone; many other compositions of this series are also known. Another step confirmatory of this existence of a series of quinones was made by Graebe and Borgmann, as the chloranil could be formed by treating phenol by potassic chlorate and hydrochlorie acid and quinone derived from it, they showed that in the next higher series to the phenol series, viz. with cressol, the same reaction held good, and by treating it in the same way they obtain a di- and a trichlorotolu-quinone $C_6\left\{\begin{matrix}CH_3\\(O_2)''\\Cl_2\\H\end{matrix}\right.$ $C_6\left\{\begin{matrix}CH_3\\(O_2)''\\Cl_3\end{matrix}\right.$ which in physical properties very closely resemble the corresponding compounds in the lower series. Other compounds have also been prepared. In the next step we have the application, which connects these series of discoveries with alizarine. Following the clue of a certain analogy which they believed to exist between the chloranilic acid $C_6Cl_2\begin{matrix}(O_2)''\\(HO)_2\end{matrix}$ and the chloroxynaphthalic acid $C_{10}H_4Cl\begin{matrix}(O)_2\\(HO)_2\end{matrix}$ which they had proved to be quinone compounds and alizarine, believing that a certain similarity of properties indicated a certain similarity of constitution, Graebe and Liebermann were lead to suppose that alizarine must also be a derivative from a quinone, and have the formula $C_{14}H_4\begin{matrix}(O_2)\\(HO_2)\end{matrix}$ This theory they were able afterward to prove; the first thing was to find the hydrocarbon from which the quinone might be derived; this was done by taking alizarine itself, and heating it with a very large excess of zinc powder in a long tube, sealed at one end. A product distilled over, and condensed in the cool part of the tube, and collecting it and purifying it by recrystallisation, they found they had not a new substance, but a hydrocarbon discovered as long ago as 1832 by Dumas and Laurent, and obtained by them from tar. They had given it the formula $C_{15}H_{12}$, and as apparently it thus contained one and a half times as many atoms of carbon and hydrogen as naphthalin did, they named it Paranaphthalin; afterwards Laurent changed its name to Anthracene, by which it is still known. Fritzsche, in 1857, probably obtained the same body, but gave it the formula $C_{14}H_{10}$. Anderson also met with it in his researches, established its composition and found some derivatives from it. Limprich in 1866 showed it could be formed synthetically by heating benzolchloride (C_7H_7Cl) with water and Berthelot has since proved that it is formed by the action of heat on many hydrocarbons. This first step was thus complete and most satisfactory; from alizarin they had obtained its hydrocarbon, and this hydrocarbon was a body already known, and with such marked properties that it was easy to identify it. But would the next requirement be fulfilled, would it like benzol and naphthalin yield a quinone? The experiment had not to be tried, for when they found that anthracene was the hydrocarbon found, they recognised in a body already known to exist, the quinone derivable from it. It had been prepared by Laurent by the action of nitric acid on anthracene, and called by him anthraceneuse, and the same substance was also discovered by Anderson and called by him oxanthracene. The composition of this body was proved by Anderson and Laurent to be $C_{14}H_8O_2$, and it thus bears the same relation to its hydrocarbon anthracene, that quinone and naphthaquinone do to their hydrocarbons. Graebe gave to it the systematic name of anthraquinone. We have then, now, three hydrocarbons C_6H_6, $C_{10}H_8$, and $C_{14}H_{10}$, differing by C_4H_2, and all forming starting points for these different quinone series. Anthroquinone acted upon by chlorine gave substitution products such as might have been foretold. It is an exceedingly stable compound, not attacked even by fusion with potassic hydrate. Bromine does not act upon it in the cold, but at 100° it forms a bibromanthraquinone. Other bromine compounds have also been found. Now, if the analogies which have guided them so far still hold good, they would seem to have the means of forming alizarine artificially. Their theory is

that it is dioxyanthraquinone $C_{14}\ H_6 \begin{matrix}(O_2)''\\(HO)_2\end{matrix}$ and if so, judging from what is known to take place with other quinone derivatives it should be formed from this dibromoanthraquinone on boiling it with potash or soda and then acidulating the solution. They try the experiment, and describe how, contrary at first to their expectations, on boiling the dibromanthraquinone with potash no change occurred, but afterwards, on using stronger potash and a higher temperature, they had the satisfaction of seeing the liquid little by little become of a violet colour; this shows the formation of alizarine. Afterwards, on acidifying this solution, the alizarine separated out in yellowish flocks. On volatalising it they got it in crystals, like those obtained from madder. On oxidising it with nitric acid, they get phthalic acid; and on precipitating it with the ordinary mordants or other metallic solutions, they get compounds exactly comparable to those from the natural product. Every trial confirms their success, so by following firmly theoretical considerations, they have been led to the discovery of the means of artificially forming this important organic colouring matter. A special interest must always attach itself to this discovery, for it is the first instance in which a natural organic colouring matter has been built up by artificial means; now the chemist can compete with Nature in its production. Although the first, it is a safe prediction that it will not long be the only one; which colouring matter will follow next it is impossible to say, but sooner or later that most interesting one, scientifically and practically, indigo will have to yield to the scientific chemist the history of its production. Returning for a moment to the percentage composition of alizarine, now that we know its constitution, its formula is established, and on comparing it ($C_{14}\ H_8\ O_4$) with all the different formulæ which have been proposed, we see that the one advocated by Schunk was most nearly correct, in fact that it differs from it only by two atoms of hydrogen. It is not without interest to note that the next most important colouring matter in madder. Purpurine, which so pertinaciously follows alizarine, is in constitution very nearly allied to it, and is also an anthraecne derivative.

Scientifically then the artificial production of this natural product was complete, but the practical question, can it be made in the laboratory cheaper than it can be obtained from the root, had yet to be dealt with. The raw material, the anthracene, a bye-product in the manufacture of coal gas, had as yet only been obtained as a chemical curiosity; it had no market value, its cost would depend on the labour of separating it from the tar, and the amount obtainable. But with regard to the bromine necessary to form the bibromanthbarquinone it was different; the use of such an expensive re-agent would preclude the process becoming a manufacturing one. But could no cheaper re-agent be used in place of the bromine, and thus crown this discovery by utilising it as a manufactunrig process? It was our countryman, Mr. Perkin, who first showed how this could be done, and has since proved the very practical and important nature of his discovery by carrying it out on the manufacturing scale. The nature of Perkin's discovery was the forming in place of a bibromanthraquinone, a disulphoanthraquinone, in a word he used sulphuric acid in place of bromine, obtaining thus a sulpho acid in place of a bromine substitution compound. The properties of these sulpho acids, containing the monovalent groups $H\ SO_3$ which is the equivalent to the atom of bromine, is that on being boiled with an alkali they are decomposed, and a corresponding alkaline salt formed; thus the change from the anthraquinone to the alizarine was effected by boiling it with sulphuric acid. At a high temperature, it dissolves, becoming a sulpho acid $C_{14}\ H_6 \left\{\begin{matrix}(O_2)''\\HSO_3\\HSO_3\end{matrix}\right.$ and the further changes follow, as they did with the bromine compound: the sulphuric acid boiled with potash is decomposed, and a potash salt of alizarin and potassic sulphite are formed; acid then precipitates the alizarin as a bright yellow substance. While Perkin was carrying on these researches in this country, Caro, Graebe, Liebermann, were carrying on somewhat similar ones in Germany; and in both countries have the scientific experiments developed into manufacturing industries. My knowledge extends only to the English manufactory, and if any excuse be necessary for having asked your attention to-day to this long history of a single substance, I think I must plead the existence of that manufactory as my excuse, for it is not often that purely scientific research so rapidly culminates in great practical undertakings. Already has the artificial become a most formidable opponent to the natural product; and in this struggle already begun there can be no doubt which will come off victorious. In the manufactory is rigidly carried out, the exact process I have already described to you. In tar there is about 1 per cent. of the anthracene; this, in a crude, impure state, is obtained from it by the tar-distiller, and sent by him to the colour works; here it is purified by pressure by dissolving from it many of its impurities, and lastly by volatalising it. Then comes the conversion of it into the anthraquirrone by oxidising agents, nitric or chromic acid being used. Then the formation of the sulphur compound by heating it with sulphuric acid to a temperature of about 260° C. The excess of acid present is then neutralised by the addition of lime, and the insoluble calcic sulphate is filtered off; to the filtered liquid sodic carbonate is added, and thus the calcic salt of the sulpho acid is changed into the sodic salt $C_{14}\ H_6 \left\{\begin{matrix}(O_2)''\\Na\ SO_3\\Na\ SO_3\end{matrix}\right.$ This is afterwards heated to about 180° C. with caustic soda, thus decomposing the sulphuric acid and forming the soda salt of alizarin; and sodic sulphite; the alizarine salt so formed, remains in solution, giving to the liquid a beautiful violet colour; from this solution sulphuric acid precipitates the alizarine as an orange yellow substance. It is allowed to settle in large tanks, and then is run in the form of a yellowish sand, which contains either 10 or 15 per cent. of dry alizarine; nt o barrels, and is in this form sent to the print works, and used much in the same way as the original ground madder was used.

This alizarine mud, as I have called it, containing but 10 per cent. of dry alizarine is equal in dyeing power to about eight times its weight of the best madder, and is the pure substance required for the dyeing in place of a complicated mixture containing certain constituents which have a positively injurious effect on the colours produced.

The scientific knowledge and energy which Mr. Perkin has brought to bear on the manufacture of this colouring matter, seems already to have worked wonders, the supply and demand for artificial alizarine are increasing at a most rapid rate, and yet the manufacture of it seems hardly to have commenced. The value of madder has much decreased, and in fact, judging by what occurred in the year of revolution and commercial depression, 1848, when the price of madder fell for a time to a point at which it was considered it would no longer remunerate the growers to produce it, that point has now been again reached, but certainly from very different reasons. Last year artificial alizarine, equal in value to about one-quarter of the madder imported into England, was manufactured in this country. This year the amount will be much larger. Thus is growing up a great industry, which far and wide must exercise most important effects; old and cumbersome processes must give way to better, cheaper, newer ones, and lastly thousands of acres of land in many different parts of the world will be relieved from the necessity of growing madder and be ready to receive some new crop. In this sense may the theoretical chemist be said even to have increased the boundaries of the globe.

SECTION C.—Geological Section

Address of the President, John Phillips, F.R.S.

More than half the life of an octogenarian separates us from the birthday of the British Association in Yorkshire; and few of those who then helped to inaugurate a new scientific power can be here to-day to estimate the work which it accomplished, and judge of the plans which it proposes to follow in future. Would that we might still have with us the wise leading of Harcourt, and the intrepid advocacy of Sedgwick, names dear to Geology and always to be honoured in Yorkshire!

The natural sciences in general, and Geology in particular, have derived from the British Association some at least of the advantages so boldly claimed at its origin: some impediments have been removed from their path; society looks with approbation on their efforts; their progress is hailed among national triumphs, though achieved for the most part by voluntary labour; and the results of their discoveries are written in the prosperous annals of our native industry. . . .

Turning from topics which involve industrial interests, to other lines of geological research, we remark how firmly since 1831 the great facts of rock-stratification, succession of life, earth-movement, and changes of oceanic areas have been

established and reduced to laws—laws, indeed, of phenomena at present, but gradually acquiring the character of laws of causation.

Among the important discoveries by which our knowledge of the earth's structure and history has been greatly enlarged within forty years, place must be given to the results of the labours of Sedgwick and Murchison, who established the Cambro-Silurian systems, and thus penetrated into ancient time-relics very far toward the shadowy limit of palæontological research. Stimulated by this success, the early strata of the globe have been explored with unremitting industry in every corner of the earth; and thus the classification and the nomenclature which were suggested in Wales and Cumberland are found to be applicable in Russia and India, America and Australia, so as to serve as a basis for the general scale of geological time, founded on organic remains of the successive ages.

This great principle, the gift of William Smith, is also employed with success in a fuller study of the deposits which stand among the latest in our history and involve a vast variety of phenomena, touching a long succession of life on the land, changes of depth in the sea, and alterations of climate. Among these evidences of physical revolution, which, if modern as geological events, are very ancient if estimated in centuries, the earliest monuments of men find place—not buildings, not inhabited caves or dwellings in dry earth-pits, not pottery or fabricated metal, but mere stones shaped in rude fashion to constitute apparently the one tool and one weapon with which, according to Prestwich, and Evans, and Lubbock, the poor inhabitant of northern climes had to sustain and defend his life.

Nothing in my day has had such a decided influence on the public mind in favour of geological research, nothing has so clearly brought out the purpose and scope of our science, as these two great lines of inquiry, one directed to the beginning, the other to the end of the accessible scale of earthly time; for thus has it been made clear that our purpose can be nothing less than to discover the history of the land, sea, and air, and the long sequence of life, and to marshal the results in a settled chronology—not, indeed, a scale of years to be measured by the rotations or revolutions of planets, but a series of ages slowly succeeding one another through an immensity of time.

There is no question of the truth of this history. The facts observed are found in variable combinations from time to time, and the interpretations of these facts are modified in different directions; but the facts are all natural phenomena and the interpretations are all derived from real laws of these phenomena—some certified by mathematical and mechanical research, others based on chemical discovery, others due to the scalpel of the anatomist, or the microscopic scrutiny of the botanist. The grandest of early geological phenomena have their representatives, however feeble, in the changes which are now happening around us; the forms of ancient life most surprising by their magnitude or singular adaptations can be explained by analogous though often rare and abnormal productions of to-day. Biology is the contemporary index of Palæontology, just as the events of the nineteenth century furnish explanations of the course of human history in the older times. . . .

During the long course of geological time the climates of the earth have changed. In many regions evidence of such change is furnished by the forms of contemporary life. Warm climates have had their influence on the land, and favoured the growth of abundant vegetations as far north as within the arctic circle; the sea has nourished reef-making corals in northern Europe during Palæozoic and Mesozoic ages; crocodiles and turtles were swimming round the coasts of Britain, among islands clothed with Zamiæ and haunted by marsupial quadrupeds. How have we lost this primæval warmth? Does the earth contribute less heat from its interior stores? does the atmosphere obstruct more of the solar rays or permit more free radiation from the land and sea? has the sun lost through immensity of time a sensible portion of its beneficent influence? or, finally, is it only a question of the elevation of mountains, the oceanic currents, and the distribution of land and sea?

The problems thus suggested are not of easy solution, though in each branch of the subject some real progress is made. The globe is slowly changing its dimensions by cooling; thus inequalities and movements of magnitude have arisen and are still in progress on its surface: the effect of internal pressure, when not resulting in mass-movement, is expressed in the molecular action of heat which Mallet applies to the theory of volcanoes. The sun has no recuperative auxiliary known to Thomson for replacing his decaying radiation; the earth, under his influence, as was shown by Herschel and Adhemar, is subject to periods of greater and less warmth, alternately in the two hemispheres and generally over the whole surface; and finally, as Hopkins has shown, by change of local physical conditions the climate of northern zones might be greatly cooled in some regions and greatly warmed in others.

One is almost frozen to silence in presence of the vast sheets of ice which some of my friends (followers of Agassiz) believe themselves to have traced over the mountains and vales of a great part of the United Kingdom, as well as over the kindred regions of Scandinavia. One shudders at the thought of the innumerable icebergs with their loads of rock, which floated in the once deeper North Sea, and above the hills of the three Ridings of Yorkshire, and lifted countless blocks of Silurian stone from lower levels, to rest on the precipitous limestones round the sources of the Ribble.

Those who, with Professor Ramsay, adopt the glacial hypothesis in its full extent, and are familiar with the descent of ice in Alpine valleys where it grinds and polishes the hardest rocks, and winds like a slow river round projecting cliffs, are easily conducted to the further thought that such valleys have been excavated by such ice-rubbers, and that even great lakes on the course of the rivers have been dug out by ancient glaciers which once extended far beyond their actual limits. That they did so extend is in several instances well ascertained and proved; that they did in the manner suggested plough out the valleys and lakes is a proposition which cannot be accepted until we possess more knowledge than has yet been attained regarding the resistance offered by ice to a crushing force, its tensile strength, the measure of its resistance to shearing, and other data required for a just estimate of the problem. At present it would appear that under a column of its own substance 1000 ft. high, ice would not retain its solidity; if so, it could not propagate a greater pressure in any direction. This question of the excavating effect of glaciers is distinctly a mechanical problem, requiring a knowledge of certain data; and till these are supplied, calculations and conjectures are equally vain.

A distinguishing feature of modern geology is the greater development of the doctrine that the earth contains in its burial-vaults, in chronological order, forms of life characteristic of the several successive periods when stratified rocks were deposited in the sea. This idea has been so thoroughly worked upon in all countries, that we are warranted to believe in something like one universal order of appearance in time, not only of large groups but even of many genera and species. The Trilobitic ages, the Ammonitic, Megalosaurian, and Palæotherian periods are familiar to every geologist. What closed the career of the several races of plants and animals on the land and in the sea, is a question easily answered for particular parts of the earth's surface by reference to "physical change;" for this is a main cause of the presence or absence, and in general of the unequal distribution of life. But what brought the succession of different races in something like a constant order, not in one tract only, but one may say generally in oceanic areas, over a large portion of the globe?

Life unfolds itself in every living thing, from an obscure, often undistinguishable cell germ, in which resides a potential of both physical and organic change—a change which, whether continual or interrupted, gradual or critical, culminates in the production of similar germs, capable under favourable conditions of assuming the energy of life.

How true to their prototypes are all the forms with which we are familiar, how correctly they follow the family pattern for centuries, and even thousands of years, is known to all students of ancient art and explorers of ancient catacombs. But much more than this is known. Very small differences separate the elephant of India from the mammoth of Yorkshire, the *Waldheimia* of the Australian shore from the *Terebratula* of the Cotswold oolite, the dragon-fly of our rivers from the *Libellula* of the Lias, and even the *Rhynchonellæ* and *Lingulæ* of the modern sea from the old species which swarm in the Palæozoic rocks.

But concurrently with this apparent perpetuity of similar forms and ways of life, another general idea comes into notice. No two plants are more than alike; no two men have more than the family resemblance; the offspring is not in all respects an exact copy of the parent. A general reference to some earlier type, accompanied by special diversity in every case ("descent with modification"), is recognised in the case of every living being.

Similitude, not indentity, is the effect of natural agencies in the continuation of life-forms, the small differences from identity being due to limited physical conditions, in harmony with the general law that organic structures are adapted to the exigencies of being. Moreover, the structures are adaptable to new conditions; if the conditions change, the structure changes also, but not suddenly; the plant or animal may survive in presence of slowly altered circumstances, but must perish under critical inversions. These adaptations, so necessary to the preservation of a race, are they restricted within narrow limits? or is it possible that in course of long-enduring time, step by step and grain by grain, one form of life can be changed and has been changed to another, and adapted to fulfil quite different functions? It is thus that the innumerable forms of plants and animals have been "developed" in the course of ages upon ages from a few original types?

This question of development might be safely left to the prudent researches of Physiology and Anatomy, were it not the case that Palæontology furnishes a vast range of evidence on the real succession in time of organic structures, which on the whole indicate more and more variety and adaptation, and in certain aspects a growing advance in the energies of life. Thus at first only invertebrate animals appear in the catalogues of the inhabitants of the sea, then fishes are added, and reptiles and the higher vertebrata succeed; man comes at last, to contemplate and in some degree to govern the whole.

The various hypothetical threads by which many good naturalists hope to unite the countless facts of biological change into an harmonious system have culminated in Darwinism, which takes for its basis the facts already stated, and proposes to explain the analogies of organic structure by reference to a common origin, and their differences to small, mostly congenital, modifications which are integrated in particular directions by external physical conditions, involving a "struggle for existence." Geology is interested in the question of development, and in the particular exposition of it by the great naturalist whose name it bears, because it alone possesses the history of the development *in time*, and it is to inconceivably long periods of time, and to the accumulated effect of small but almost infinitely numerous changes in certain directions, that the full effect of the transformations is attributed.

For us, therefore, at present it is to collect with fidelity the evidence which our researches must certainly yield, to trace the relation of forms to time generally and physical conditions locally, to determine the life-periods of species, genera, and families in different regions, to consider the cases of temporary interruption and occasional recurrence of races, and how far by uniting the results obtained in different regions the alleged "imperfection of the geological record" can be remedied.

The share which the British Association has taken in this great work of actually reconstructing the broken forms of ancient life, of repeopling the old land and older sea, of mentally reviving, one may almost say, the long-forgotten past, is considerable, and might with advantage be increased. We ask, and wisely, from time to time, for the combined labour of naturalists and geologists in the preparation of reports on particular classes or families of fossil plants and animals, their true structure and affinities, and their distribution in geological time and geographical space. Some examples of this useful work will, I hope, be presented to this meeting. Thus have we obtained the aid of Agassiz and Owen, and have welcomed the labours of Forbes and Morris, and Lycett, and Huxley, of Dawkins and Egerton, of Davidson, Duncan, and Wright, of Williamson and Carruthers and Woodward, and many other eminent persons, whose valuable results have for the most part appeared in other volumes than our own.

Among these volumes let me in a special manner recall to your attention the priceless gift to Geology which is annually offered by the Palæontographical Society, a gift which might become even richer than it is, if the literary and scientific part of our community were fortunate enough to know what a perpetual treasure they might possess in return for a small annual tribute. The excellent example set and the good work recorded in the Memoirs of the Society referred to have not been without influence on foreign men of science. We shall soon have such Memoirs from France and Italy, Switzerland and Germany, America and Australia; and I trust the effect of such generous rivalry will be to maintain and increase the spirit of learned research and of original observation which it is our privilege and our duty to foster, to stimulate, and to combine.

On all the matters, indeed, which have now been brought, to your thoughts the one duty of geologists is to collect more and more accurate information; the one fault to be avoided is the supposition that our work in any department is complete. We should speak modestly of what has been done; for we have completed nothing, except the extinction of a crowd of errors, and the discovery of right methods of proceeding toward the acquisition of truth. We may speak hopefully of what is to be accomplished; for the right road is before us. We have taken some steps along it; others will go beyond us and stand on higher levels. But it will be long before anyone can reach the height from which he may be able to survey the whole field of research and collect the results of ages of labour.

SECTION D.—Biology

Opening Address by the President, Prof. Allman

The present Aspects of Biology and the Method of Biological Study

For some years it has been the practice at the meetings of this Association for the special presidents to open the work of their respective sections with an address which is supposed to differ, in the greater generality of its subject, from the ordinary communications to the sections. Finding that during the present meeting this duty would devolve on myself, I thought over the available topics, and concluded that a few words on the present aspect of Biology and the method of Biological Study would best satisfy the conditions imposed.

I shall endeavour to be as little technical as my subject will allow, and though I know that there are here present many to whom I cannot expect to convey any truths with which they are not already familiar, yet in an address of this kind the speaker has no right to take for granted any large amount of scientific knowledge in his audience. Indeed, one of the chief advantages which result from these meetings of the British Association consists in the stimulus they give to inquiry—in the opportunity they afford to many of becoming acquainted for the first time with the established truths of Science, and the initiation among them of new lines of thought.

And this is undoubtedly no small gain; for how many are there who, though they may have reaped all the advantages which our established educational systems can bestow, are yet sadly deficient in a knowledge of the world of life which surrounds them. It is a fair and wonderful world, this on which we have our dwelling-place, and yet how many wander over it unheedingly? by how many have its lessons of wisdom never been read? how many have never spared a thought on the beauty of its forms, the harmony of its relations, the deep meaning of its laws?

And with all this there is assuredly implanted in man an undying love of such knowledge. From his unshaken faith in causation he yearns to deduce the unknown from the known, to look beyond what is at hand and obvious to what is remote and unseen.

Conception of Biology and Function of the Scientific Method

Under the head of Biology are included all those departments of scientific research which have as their object the investigation of the living beings—the plants and the animals—which tenant the surface of our earth, or have tenanted it in past time.

It admits of being divided under two grand heads: Morphology, which treats of Form, and Physiology, which treats of Function; and besides these there are certain departments of Biological study to which both Morphology and Physiology contribute, such as Classification, Distribution, and that department of research which is concerned with the origin and causes of living and extinct forms.

By the aid of observation and experiment we obtain the elements which are to be combined and developed into a science of living beings, and it is the function of the scientific method to indicate the mode in which the combinations are to be effected, and the path which the development must pursue. Without it the results gained would be but a confused assemblage of isolated facts and disconnected phenomena; but aided by a philosophic method, the observed facts become scientific propositions, what was apparently insignificant becomes full of meaning, and we get glimpses of the consummate laws which govern the whole.

Importance of Anatomy

The first step in our morphological study of human beings is to obtain an accurate and adequate knowledge of the forms of the individual objects which present themselves to us in our contemplation of the animal and vegetable kingdoms. For such knowledge, however, much more is needed than an acquaintance with their external figure. We must subject them to a searching scrutiny; we must make ourselves familiar with their anatomy, which involves not only a knowledge of the forms and disposition of their organs, internal as well as external, but of their histology, or the microscopic structure of the tissues of which these organs, are composed. Histology is nothing more than Anatomy carried to its extreme term, to that point where it meets with the Morphological Unit, the ultimate element of form, and the simplest combinations of this out of which all the organs in the living body are built up.

Among the higher animals Anatomy, in the ordinary sense of the word, is sufficiently distinct from Histology to admit of separate study; but in the lower animals and in plants the two become confounded at so many points as to render their separate study often impracticable.

Now the great prominence given to Anatomy is one of the points which most eminently distinguish the modern schools of Biology.

Development

Another order of morphological facts of scarcely less importance than those obtained from anatomical study is that derived from the changes of form which the individual experiences during the course of its life. We know that every organised being commences existence as a simple sphere of protoplasm, and that from this condition of extreme generalisation all but the very lowest pass through phases of higher and higher specialisation acquiring new parts and differentiating new tissues. The sum of these changes constitutes the development of the organisms, and no series of facts is more full of significance in its bearing on Biological Science than that which is derived from the philosophical study of Development.

Classification an Expression of Affinities

Hitherto we have been considering the individual organism without any direct reference to others. But the requirements of the biological method can be satisfied only by a comparison of the various organisms one with the other. Now the grounds of such comparison may be various, but what we are at present concerned with will be found in anatomical structure and in developmental changes; and in each of these directions facts of the highest order and of great significance become apparent.

By a carefully regulated comparison of one organism with another, we discover the resemblances as well as the differences between them. If these resemblances be strong, and occur in important points of structure or development, we assert that there is an affinity between the compared organisms, and we assume that the closeness of the affinity varies directly with the closeness of the resemblance.

It is on the determination of these affinities that all philosophic classification of animals and plants must be based. A philosophical classification of organised beings aims at being a succinct statement of the affinities between the objects so classified, these affinities being at the same time so set forth as to have their various degrees of closeness and remoteness indicated in the classification.

Affinities have long been recognised as the grounds of a natural biological classification, but it is only quite lately that a new significance has been given to them by the assumption that they may indicate something more than simple agreement with a common plan—that they may be derived by inheritance from a common ancestral form, and that they therefore afford evidence of a true blood relationship between the organisms presenting them.

The recognition of this relationship is the basis of what is known as the Descent Theory. No one doubts that the resemblances we notice among the members of such small groups as those we name species are derived by inheritance from a common ancestor, and the Descent Theory is simply the extension to the larger groups of this same idea of relationship.

If this be a true principle, then biological classification becomes an exposition of family relationship—a genealogical tree in which the stem and branches indicate various degrees of relationship and direct and collateral lines of descent. It is this conception which takes classification out of the domain of the purely Morphological.

Affinity determined by the Study of Anatomy and Development

From what has just been said it follows that it is mainly by a comparison of organisms in their anatomical and developmental characters that their affinities are discoverable. The structure of an organism will in by far the greater number of cases be sufficient to indicate its true affinity, but it sometimes happens that certain members of a group depart in their structure so widely from the characters of the type to which they belong, that without some other evidence of their affinities no one would think of assigning them to it. This evidence is afforded by development.

An example or two will serve to make the subject clear, and we shall first take one from a case where, without a knowledge of anatomical structure, we should easily go astray in our attempts to assign to the forms under examination their true place in the classification.

If we search our coasts at low water we shall be sure to meet with certain plant-like animals spreading over the rocks or rooted to the fronds of sea-weeds, all of which present so close a resemblance to one another as to have led to their being brought together into a single group to which, under the name of "Polypes," a definite place was assigned in the classification of the animal kingdom.

They are all composite animals consisting of an association of buds or zooids, which remain organically united to one another, and give to the whole assemblage the appearance in many cases of a little branching tree. Every bud carries a delicate transparent cup of chitine within which is contained the principal part of the animal, and from which this has the power of spontaneously protruding itself; and when thus protruded it will be seen to present a beautiful crown of tentacles surrounding a mouth through which food is taken into a stomach. As long as no danger threatens, the little animal will continue displayed with its beautiful corona of tentacles expanded; but touch it ever so lightly, and it will instantly close up its tentacles, retract its whole body, and take refuge in the recesses of the protecting cup.

So far then there is a complete agreement between the animals which have been thus associated under the designation of Polypes, and in all that concerns their external form no one point can be adduced in opposition to the justice of this association. When, however, we pass below the surface and bring the microscope and dissecting needle to bear on their internal organisation, we find that among the animals thus formed so apparently alike, we have two totally distinct types of structure; that while in one the mouth leads into a simple excavation of the body on which devolves the whole of the functions which represent digestion, in the other there is a complete alimentary tract entirely shut off from the proper cavity of the body and consisting of distinctly differentiated œsophagus, stomach, and intestine; while in the one the muscular system consists of an indistinct layer of fibres intimately united in its whole extent with the body walls, in the other there are distinctly differentiated free bundles of muscles for the purpose of effecting special motions in the economy of the animal; while in the one no differentiated nervous system can be detected, in the other there is a distinct nervous ganglion with nervous filaments. In fact the two forms are shown by a study of their anatomical structure to belong to two entirely different primary divisions of the animal kingdom; for while the one has a close affinity with the little fresh-water Hydra, and is therefore referred to the Hydroida among the sub-kingdom Cœlenterata, the other is referable to the group of the Polyzoa; it has its immediate affinities with the Ascidians, and belongs to the sub-kingdom of the Mollusca.

We shall next take an example in which the study of development rather than of anatomy affords the clue to the true affinities of the organism.

Attached to the abdomen of various crabs may often be seen certain soft fleshy sacs to which the name of *Sacculina* has been given. They hold their place by means of a branching root-like extension which penetrates the abdomen of the crab and winds itself round its intestine or dives into its liver, within which its fibres ramify like the roots of a tree.

Now the question at once presents itself: what position in the animal kingdom are we to assign to this immoveably rooted sac destitute of mouth and of almost every other organ with which we are in the habit of associating the structure of an animal?

Anatomy will here be powerless in helping us to arrive at a

conclusion, for the dissecting knife shows us little more than a closed sac filled with eggs and fixed by its tenacious roots in the viscera of its victim. Let us see, however, what we learn from development. If some of the eggs with which the Sacculina is filled be placed in conditions suited to their development, they give origin to a form as different as can well be imagined from the sacculina. It is an active, somewhat oval-shaped little creature, covered with a broad dorsal shield or carapace, and furnished with two pairs of strong swimming feet which carry long bristles, and also with a pair of anterior limbs or antennæ. It is, in fact, identical with a form known to zoologists by the name "Nauplius," and which has been proved to be one of the young states of the Barnacle and of other lower crustacea; while even some of the higher crustacea have been observed to pass through a similar stage.

After a short time the Nauplius of our Sacculina changes its form; the carapace folds down on each side and assumes the shape of a little bivalve shell; while six new pairs of swimming feet are developed. The little animal continues its active natatory life, and in this stage it is again identical in all essential points with one of the young stages of the Barnacle.

In the meantime a remarkable change takes place in the two antennæ; they become curiously branched and converted into prehensile organs. The young Sacculina now seeks the crab on which it is to spend parasitically the rest of its life; it loses its bivalve shell, the prehensile antennæ takes hold of its victim, penetrates the soft skin of its abdomen in order to seek within it the nutriment with which it can be there so plentifully supplied, locomotion is gone for ever, and the active and symmetrical Nauplius becomes converted into the inert and shapeless Sacculina.

The nearest affinities of Sacculina are thus undoubtedly with the Barnacles, which have been proved both on anatomical and developmental grounds to belong to the great division of the Crustacea.

A Philosophical Classification cannot form a single Rectilineal Series

A comparison of animals with one another having thus resulted in establishing their affinities, we may arrange them into groups, some more nearly, others more remotely related to one another. The various degrees and directions of affinity will be expressed in every philosophical arrangement, and as these affinities extend in various directions, it becomes at once apparent that no arrangement of the animal or vegetable kingdom in a straight line ascending like the steps of a ladder from lower to higher forms, can give a true idea of the relations of living beings to one another. These relations, on the contrary, can be expressed only by a ramified and complex figure which we have already compared to that of a genealogical tree.

Homology

In the comparison of organised beings with one another, certain relations of great interest and significance become apparent between various organs. These are known by the name of Homologies, and organs are said to be homologous with one another when they can be proved to be constructed on the same fundamental plan, no matter how different they may be in form and in the functions which they may be destined to execute. Organs not constructed on the same fundamental plan may yet execute similar functions, and then, whether they do or do not resemble one another in form, they are said to be merely analogous; and some of the most important steps in modern Biology have resulted from attention to the distinction between Homology and Analogy, a distinction which was entirely disregarded by the earlier schools.

The nature of Homology and its distinction from Analogy will be best understood by a few examples.

Compare the wing of a bird with that of an insect; there is a resemblance between them in external form; there is also an identity of function, both organs being constructed for the purpose of flight, and yet they are in no respect homologous, for they are formed on two distinct plans which have nothing whatever in common. The relation between them is that simply of analogy.

On the other hand, no finer illustrations of Homology can be adduced than those which are afforded by a comparison with one another of the anterior limbs among the various members of the vertebrata. Let us compare, for example, the bird's wing with the anterior limb of man. Here we have two organs between which the ordinary observer would fail to recognise any resemblance—organs, too, whose functions are entirely different, one being formed for prehension and the other for flight. When, however, they are compared in the light which a philosophic anatomy is capable of throwing on them, we find, between the two, a parallelism which points to one fundamental type on which they are both constructed.

There is first the shoulder-girdle, or system of bones by which, in each case, the limb is connected with the rest of the skeleton. Now this part of the skeleton in man is very different in form from the same part in the bird, and yet a critical comparison of the two shows us that the difference mainly consists in the fact that the coracoid which in man is a mere process of the scapula, is in the bird developed as an independent bone; and in the further fact that the two clavicles in man are, in the bird, united into a single V-shaped bone or "furcula." Then, if we can compare the arm, fore-arm, wrist, and hand in the human skeleton with the various parts which follow one another in the same order in the skeleton of the bird's wing, we shall find between the two series a correspondence which the adaptations to special functions may in some regions mask, but never to such an extent as to render the fundamental unity of plan difficult of detection by the method of the higher anatomy. As far as regards the arm and fore-arm, these in the bird are nearly repetitions of their condition in the human skeleton; but the parts which follow appear at first sight so different as to have but little relation with one another, and yet a common line can be traced with great distinctness through the two. Thus the wrist is present in the bird's wing as well as in the anterior limb of man, but while in man it is composed of eight small irregularly-shaped bones arranged in two rows, in the wing it has become greatly modified, the eight bones being reduced to two. Lastly, the hand is also represented in the wing, where it constitutes a very important part of the organ of flight, but where it has undergone such great modification as to be recognisable only after a critical comparison; for the five metacarpal bones of the human hand are reduced to two consolidated with one another at their proximal and distal ends; and then the five fingers of the hand are reduced in the wing to three, which represent the middle finger, fore-finger, and thumb. The fore-finger in the bird consists of only one phalanx, the middle of two, and the thumb forms a small stiletto-like bone springing from the proximal end of the united metacarpals.

In the case now adduced we have an example of the way in which the same organ in two different animals may become very differently modified in form, so as to fit it for the performance of two entirely different functions, and yet retain sufficient conformity to a common plan to indicate a fundamental unity of structure.

Let us take another example, and this I shall adduce from the vegetable kingdom, which is full of beautiful instances of the relations with which we are now occupied.

There are the parts known as tendrils, thread-like organs, usually rolling themselves into spirals, and destined, by twining round some fixed support, to sustain climbing plants in their efforts to raise themselves from the ground. We shall take two examples of these beautiful appendages, and endeavour to determine their homological significance.

There is the genus *Smilax*, one species of which adorns the hedges of the south of Europe, where it takes the place of the Bryony and *Tamus* of our English country lanes. From the point where the stalks of its heart-shaped leaves spring from the stem, there is given off a pair of tendrils by means of which the Smilax clings to the surrounding vegetation in an inextricable entanglement of branches and foliage.

With the tendrils of the Smilax let us compare those of the *Lathyrus aphaca*, a little vetch occasionally met with in waste places and the margins of corn-fields. The leaves are represented by arrow-shaped leaf-like appendages, which are placed opposite to one another in pairs upon the stem, but instead of each of these carrying two tendrils at its origin like the leaves of the Smilax, a single tendril springs from the middle point between each pair.

The tendrils in the two cases, though similar in appearance and in function, differ thus in number and arrangement, and the questions occur: are they homologous with one another, or are they only analogous? and if they be only analogous, can we trace between them and any other organ homologous relations?

To enable us to decide on this point, we must bear in mind that a leaf when typically developed consists of three portions, the lamina or blade, the petiole or leaf-stalk, and a pair of

foliaceous appendages or stipules, which are placed at the base of the leaf-stalk. Now this typical leaf affords the key to the homologies of the tendrils in the two cases under examination.

Take the Smilax: in this case there are no stipules of the ordinary form, but the two tendrils hold exactly the position of the stipules in our type-leaf, and must be regarded as representing them. We have only to imagine these stipules so modified in their form as to become reduced to two long spiral threads, and we shall at once have the tendrils of the Smilax; on the other hand let the stipules in our type remain as leaf-like organs, and let the rest of the leaf—the lamina and petiole—lose its normal character, and become changed into a spiral thread, and we shall then have the stipules of our type-leaf retained in the two opposite leaf-like organs of the Lathyrus, while the remainder of the type-leaf will present itself in the condition of the Lathyrus tendril which springs from the central point between them.

The tendrils of the Smilax and of the *Lathyrus aphaca* are thus not homologous with one another, but only analogous, while those of the Smilax are homologous with a pair of stipules and those of the Lathyrus homologous with the lamina and petrile of a leaf.

Besides the homology discoverable between the organs of different animals and plants, a similar relation can be traced between organs in the same animal or plant; as, for example, that between the different segments of the vertebral column, which can be shown to repeat one another homologically; and that between the parts composing the various verticils of the flower and the leaves in the plant.

The existence of homological relations such as have been just illustrated admits of an easy explanation by the application of the doctrine of descent, according to which the two organs compared would originate from a common ancestral form. In accordance with this hypothesis, homology would mean an identity of genesis in two organs, as analogy would mean an identity of function.

Distribution and Evolution

Another very important department of biological science is that of the Distribution of organised beings. This may be either Distribution in Space, Geographical Distribution: or Distribution in Time, Palæontological Distribution. Both of these have of late years acquired increased significance, for we have begun to get more distinct glimpses of the laws by which they are controlled, of the origin of Faunas and Floras, and of the causes which regulate the sequence of life upon the earth. Time, however, will not allow me to enter upon this subject as fully as its interest and importance would deserve, and a few words on Palæontological Distribution is all that I can now venture on.

The distribution of organised beings in time has lately come before us in a new light by the application to it of the hypothesis of evolution. According to this hypothesis, the higher groups of organised beings now existing on the earth's surface have come down to us with gradually increasing complexity of structure by continuous descent from forms of extreme simplicity which constituted the earliest life of our planet.

In almost every group of the animal kingdom the members which compose it admit of being arranged in a continuous series passing down from more specialised, or higher, to more generalised or lower forms; and if we have any record of extinct members of the group, the series may be carried on through these. Now while the descent hypothesis obliges us to regard the various terms of the series as descended from one another, the most generalised forms will be found among the extinct ones, and the further back in time we go the simpler do the forms become.

By a comparison of the forms so arranged we obtain as it were the law of the series, and can thus form a conception of the missing terms and continue the series backwards through time, even where no record of the lost forms can be found, until from simpler to still simpler terms we at last arrive at the conception of a term so generalised that we may regard it as the primordial stock, the ancestral form from which all the others have been derived by descent.

This root form is thus not actually observed, but is rather obtained by a process of deduction, and is therefore hypothetical. We shall strengthen, however, its claims to acceptance by the application of another principle. The study of embryology shows that the higher animals, in the course of their development, pass through transitory phases which have much in common with the permanent condition of lower members of the type to which they belong, and therefore with its extinct representatives. We are thus enabled to lay down the further principle that the individual, in the course of its own development from the egg to the fully formed state, recapitulates within that short period of time the various forms which its ancestry presented in consecutive epochs of the world's history; so that if we knew all the stages of its individual development, we should have a long line of its descent. Through the hypothesis of evolution, palæontology and embryology are thus brought into mutual bearing on one another.

Let us take an example in which these two principles seem to be illustrated. In rocks of the Silurian age there exist in great profusion the remarkable fossils known as graptolites. These consist of a series of little cups or cells arranged along the sides of a common tube, and the whole fossil presents so close a resemblance to one of the Sertularian hydroids which inhabit the waters of our present seas as to justify the suspicion that the graptolites constitute an ancient and long since extinct group of the Hydroida. It is not, however, with the proper cells or hydrothecæ of the Sertularians that the cells of the graptolite most closely agree, but rather with the little receptacles which in certain Sertularinæ belonging to the family of the Plumularida we find associated with the hydrothecæ, and which are known as "Nematophores," a comparison of structure then shows that the graptolites may with considerable probability be regarded as representing a Plumularia in which the hydrothecæ had never been developed and in which their place had been taken by the nematophores.

Now it can be shown that the nematophores of the living Plumularida are filled with masses of protoplasm which have the power of throwing out pseudopodia, or long processes of their substance, and that they thus resemble the Rhizopoda, whose soft parts consist entirely of a similar protoplasm and which stand among the Protozoa or lowest group of the animal kingdom. If we suppose the hydrotheca suppressed in a plumularian, we should thus nearly convert it into a colony of Rhizopoda, from which it would differ only in the somewhat higher mophological differentiation of its cænosarc or common living bond by which the individuals of the colony are organically connected. And just such a colony would, under this view, a graptolite be, waiting only for the development of hydrotheca to raise it into the condition of a plumularian.

Bringing now the evolution hypothesis to bear upon the question, it would follow that the graptolite may be viewed as an ancestral form of the Sertularian hydroids, a form having the most intimate relations with the Rhizopoda; that hydranths and hydrothecæ became developed in its descendants; and that the rhizopodal graptolite became thus converted in the lapse of ages into the hydroidal Sertularian.

This hypothesis would be strengthened if we found it agreeing with the phenomena of individual development. Now such Plumularida as have been followed in their development from the egg to the adult state do actually present well-developed nematophores before they show a trace of hydrothecæ, thus passing in the course of their embryological development through the condition of a graptolite, and recapitulating within a few days stages which it took incalculable ages to bring about in the palæontological development of the tribe.

I have thus dwelt at some length on the doctrine of evolution because it has given a new direction to biological study and must powerfully influence all future researches. Evolution is the highest expression of the fundamental principles established by Mr. Darwin, and depends on the two admitted faculties of living beings—*heredity*, or the transmission of characters from the parent to the offspring; and *adaptivity*, or the capacity of having these characters more or less modified in the offspring by external agencies, or it may be by spontaneous tendency to variation.

The hypothesis of evolution may not, it is true, be yet established on so sure a basis as to command instantaneous acceptance, and for a generalisation of such vast significance no one can be blamed for demanding for it a broad and indisputable foundation of facts. Whether, however, we do or do not accept it as firmly established, it is at all events certain that it embraces a greater number of phenomena and suggests a more satisfactory explanation of them than any other hypothesis which has yet been proposed.

With all our admiration, however, for the doctrine of Evolution as one of the most fertile and comprehensive of philosophic hypotheses, we cannot shut our eyes to the difficulties which lie

n the way of accepting it to the full extent which has been sometimes claimed for it. It must be borne in mind that though among some of the higher vertebrata we can trace back for some distance in geological time a continuous series of forms which may safely be regarded as derived from one another by gradual modification—as has been done, for example, so successfully by Prof. Huxley in the case of the horse—yet the instances are very few in which such a sequence has been actually established; while the first appearance in the earth's crust of the various classes presents itself in forms which by no means belong to the lowest or most generalised of their living representatives. On this last fact, however, I do not lay much stress, for it will admit of explanation by referring it to the deficiency of the geological record, and then demanding a lapse of time—of enormous length, it is true—during which the necessary modifications would be in progress before the earliest phase of which we have any knowledge could have been reached.

Again, we must not lose sight of the hypothetical nature of those primordial forms in which we regard the branches of our genealogical tree as taking their origin; and while the doctrine of the recapitulation of ancestral forms has much probability, and harmonises with the other aspects of the Evolution doctrine into a beautifully symmetrical system, it is one for which a sufficient number of actually observed facts has not yet been adduced to remove it altogether from the region of hypothesis.

Even the case of the graptolites already adduced is an illustration rather than a proof, for the difficulty of determining the true nature of such obscure fossils is so great that we may be altogether mistaken in our views of their structure and affinities.

To me, however, one of the chief difficulties in the way of the doctrine of Evolution, when carried out to the extreme length for which some of its advocates contend, appears to be the unbroken continuity of inherited life which it necessarily requires through a period of time whose vastness is such that the mind of man is utterly incapable of comprehending it. Vast periods, it is true, are necessary in order to render the phenomena of Evolution possible; but the vastness which the antiquity of life, as shown by its remains in the oldest fossiliferous strata, requires us to give to these periods may be even greater than is compatible with continuity.

We have no reason to suppose that the reproductive faculty in organised beings is endowed with unlimited power of extension, and yet to go no farther back than the Silurian period—though the seas which bore the Eozoon were probably as far anterior to those of the Silurian as these are anterior to our own—the hypothesis of Evolution requires that in that same Silurian period the ancestors of the present living forms must have existed, and that their life had continued by inheritance through all the ramifications of a single genealogical tree down to our own time; the branches of the tree, it is true, here and there falling away, with the extinction of whole genera and families and tribes, but still some always remaining to carry on the life of the base through a period of time to all intents and purposes infinite. It is true that in a few cases a continuous series of forms regularly passing from lower to higher degrees of specialisation, and very probably connected to another by direct descent, may be followed through long geological periods, as for example, the graduated series already alluded to, which may be traced between certain mammals of the Eocene and others living in our own time, as well as the very low forms which have come down to us apparently unmodified from the epoch of the Chalk. But incalculably great as are these periods, they are but as the swing of the pendulum in the Millennium, when compared to the time which has elapsed since the first animalisation of our globe.

Is the faculty of reproduction so wonderfully tenacious as all this, that through periods of inconceivable duration, and exposed to influences the most intense and the most varied, it has still come down to us in an unbroken stream? Have the strongest which had survived in the struggle for existence necessarily handed down to the strongest which should follow them the power of continuing as a perpetual heirloom the life which they had themselves inherited? Or have there been many total extinctions and many renewals of life—a succession of genealogical trees, the earlier ones becoming old and decayed, and dying out, and their place taken by new ones which have no kinship with the others? Or, finally, is the doctrine of Evolution only a working hypothesis which, like an algebraic fiction, may yet be of inestimable value as an instrument of research? For as the higher calculus becomes to the physical inquirer a power by which he unfolds the laws of the inorganic world, so may the hypothesis of Evolution, though only a hypothesis, furnish the biologist with a key to the order and hidden forces of the world of life. And what Leibnitz and Newton and Hamilton have been to the physicist, is it not that which Darwin has been to the biologist?

But even accepting as a great truth the doctrine of Evolution, let us not attribute to it more than it can justly claim. No valid evidence has yet been adduced to lead us to believe that inorganic matter has become transformed into living, otherwise than through the agency of a pre-existing organism, and there remains a residual phenomenon still entirely unaccounted for. No physical hypothesis founded on any indisputable fact has yet explained the origin of the primordial protoplasm, and, above all, of its marvellous properties which render Evolution possible.

Accepting, then, the doctrine of Evolution in all freedom and in all its legitimate consequences, there remains, I say, a great residuum unexplained by physical theories. Natural Selection, the Struggle for Existence, the Survival of the Fittest, will explain much, but they will not explain all. They may offer a beautiful and convincing theory of the present order and fitness of the organic universe, as the laws of attraction do of the inorganic, but the properties with which the primordial protoplasm is endowed—its heredity and its adaptivity—remain unexplained by them, for these properties are their cause and not their effect.

For the cause of this cause we have sought in vain among the physical forces which surround us, until we are at last compelled to rest upon an independent volition, a far-seeing intelligent design. Science may yet discover even among the laws of Physics the cause it looks for; it may be that even now we have glimpses of it; that those forces among which recent physical research has demonstrated so grand a unity—Light, Heat, Electricity, Magnetism—when manifesting themselves through the organising protoplasm, become converted into the phenomena of life, and that the poet has unconsciously enunciated a great scientific truth when he tells us of

> "Gay lizards glittering on the walls
> Of ruined shrines, busy and bright
> As though they were *alive with light*."

But all this is only carrying us one step back in the grand generalisation. All science is but the intercalation of causes, each more comprehensive than that which it endeavours to explain, between the great primal cause and the ultimate effect.

I have thus endeavoured to sketch for you in a few broad outlines the leading aspects of biological science, and to indicate the directions which biological studies must take. Our science is one of grand and solemn import, for it embraces man himself and is the exponent of the laws which he must obey. Its subject is vast, for it is Life, and Life stretches back into the illimitable past, and forward into the illimitable future. Life, too, is everywhere. Over all this wide earth of ours, from the equator to the poles, there is scarcely a spot which has not its animal or its vegetable denizens—dwellers on the mountain and on the plain, in the lake and on the prairie, in the arid desert and the swampy fen; from the tropical forest with its strange forms and gorgeous colours, and myriad voices, to the ice-fields of polar latitudes and those silent seas which lie beneath them, where living things unknown to warmer climes congregate in unimaginable multitudes. There is life all over the solid earth; there is life throughout the vast ocean, from its surface down to its great depths, deeper still than the lead of sounding-line has reached.

And it is with these living hosts, unbounded in their variety, infinite in their numbers, that the student of biology must make himself acquainted. It is no light task which lies before him—no mere pastime on which he may enter with trivial purpose, as though it were but the amusement of an hour; it is a great and solemn mission to which he must devote himself with earnest mind and with loving heart, remembering the noble words of Bacon:—

"Knowledge is not a couch whereon to rest a searching and restless spirit; nor a terrace for a wandering and variable mind to walk up and down with a fair prospect; nor a tower of state for a proud mind to raise itself upon; nor a fort or commanding-ground for strife and contention; nor a shop for profit and sale; but a rich storehouse for the glory of the Creator, and the relief of man's estate."

SECTION G.—Mechanical Science

Opening Address by the President, W. H. Barlow, C.E., F.R.S.

In the observations which I have to address to you I shall not attempt a general survey of a subject so vast and so varied as the manufactures of this country, nor shall I attempt to describe the many new and beautiful inventions and mechanical appliances which form a distinguishing feature of the age in which we live; but I shall endeavour to draw your attention to one of the new materials, namely *modern steel*—a material which, though of comparatively recent origin, has already become an important industry, and whose influence in the future seems destined to vie in importance with that resulting from the introduction of iron.

I have used the term "modern steel," because, although the great movement in simplifying and cheapening the process of producing steel is necessarily associated with the name of Mr. Bessemer, yet we have further important steps taken in a forward direction as to the production and treatment of steel by Dr. Siemens and Sir Joseph Whitworth and others, both in this country and abroad.

It is now seventeen years since Mr. Bessemer read a paper at the meeting of the British Association at Cheltenham, which was entitled, "On the Manufacture of Iron and Steel without Fuel."

It is satisfactory to know that Mr. Bessemer has often expressed his firm conviction that had it not been for the publicity given to his invention through the paper which he read before the Mechanical Section of the British Association in 1856, and the great moral support afforded him by men of science whose attention was thereby directed to it, he believes that he would not have succeeded in overcoming the strong opposition with which his invention was met in other quarters.

About this time, or perhaps a little later, a material was produced called "puddled steel," and about the same time the metal known as "homogeneous iron."

The movement which had begun in the production of cheap steel was further assisted and developed by the regenerative furnace of Dr. Siemens, by the introduction of the Siemens-Martin process of making steel, and further and most important progress is suggested by the recent process introduced by Dr. Siemens in making steel direct from the ore.

According to the returns published by the Jury of the International Exhibition of 1852, the total annual produce of steel in Great Britain at that time was 50,000 tons. At the present time there are more than 500,000 tons made by the Bessemer process alone, added to which Messrs. Siemens's works at Landore produce 200,000 tons, besides further quantities which are made by his process at Messrs. Vickers, Messrs. Cammells, the Dowlais, and other works.

I shall not, however, detain you by attempting to trace up the history and progress of steel, nor attempt to notice the various steps by which this branch of industry has been brought to its present important position. My object is to draw attention to this material as to its use and application for *structural and engineering* purposes.

The steel produced by the Bessemer process was at a very early stage employed in rails and wheel-tires. In both these applications the object sought was endurance to resist the effects of wear, and toughness to prevent fracture by blows. There does not exist at present sufficient information to determine accurately the relative values of steel and iron when used for these purposes. As used for wheel-tires, steel had to compete with iron of the highest quality, but it is nevertheless introduced on most of our railways. The iron used in rails was not of such a high quality, and the difference in duration shows a very marked advantage in the employment of steel, the duration of steel rails being variously estimated at from three to six times that of iron.

Steel is also extensively used for ships' plates, and by the War Department for lining the interior of the heaviest guns; while Sir Joseph Whitworth and Messrs. Krupp make guns entirely of steel, though for these purposes the metal is of different quality and differently treated, in order to withstand the enormous concussions to which it is subjected.

And, further, we have steel used in railway-axles, crank-axles for engines, in boilers, in piston-rods, in carriage-springs, and for many other purposes.

But notwithstanding these various employments of steel, there has been, and there continues to be, a difficulty in applying it to engineering structures in this country.

The want of knowledge of the physical properties of steel having been the subject of remark at a discussion at the Institution of Civil Engineers in 1868, a committee, composed of Mr. Fowler, Mr. Scott Russell, Captain Galton, Mr. Berkley, and myself, undertook to conduct a series of experiments upon this subject.

The first were made for the Committee by Mr. Kirkaldy with his testing-machine in London, and were chiefly directed to ascertain the relation which subsists between the resistance of tension, compression, torsion, and transverse strain.

In this series of experiments twenty-nine bars, 15 ft. long, were used, each bar being cut into lengths, and turned or planed into suitable forms for the respective tests, so that a portion of each bar was subjected to each of the above-mentioned tests.

The tensile resistance varied in the different qualities of steel from 28 to 48 tons per inch, and the experiments established conclusively that the relation subsisting between the several resistances of tension, compression, and transverse strain is throughout practically the same as in wrought-iron; that is to say, that a bar of steel whose tensile strength is 50 per cent. above that of wrought-iron will exhibit about the same relative increase of resistance under the other tests.

They further showed that the limit of elasticity in steel is, like that of wrought-iron, rather more than half its ultimate resistance. The total elongation under tensile strain, and the evidences of malleability and toughness, will be referred to hereafter.

The second series recorded in the book published by the Committee gave the results of tempering steel in oil and water. They were made by the officers of the gun-factory at the Royal Arsenal at Woolwich, and show a remarkable increase of strength obtained by this process. This property of steel is now fully recognised and made use of in the steel which forms the lining of the largest guns.

The third series of experiments was made by the Committee upon bars 14 ft. long, $1\frac{1}{2}$ in. in diameter, with the skin upon the metal as it came from the rolls.

The object of these experiments was specially directed to ascertain the *modulus of elasticity*. They were made with the testing-machine at H.M. Dockyard at Woolwich, which machine was placed at our disposal by the Admiralty. The bars were obtained, with some exceptions, in sets of six from each maker, three bars of each set being used in tension and three in compression.

Bars of iron of like dimensions were also tested in the same way, in order to obtain the relative effects in steel and iron. In these experiments sixty-seven steel bars were tested whose tensile strength varied from 32 to 53 tons per inch, and twenty-four iron bars varying from 22 to 29 tons per inch.

The amount of the extensions and compressions were ascertained by *direct measurement*, verniers being for this purpose attached to the bar itself, 10 ft. apart, so that the readings gave the absolute extensions and compressions of this length of the bar.

These experiments, which were very accurately made, showed that the extension and compression of steel per ton per inch was a little less than wrought-iron, that the extension and compression were very nearly equal to each other, and that the modulus of elasticity of steel may be taken at 30,000,000, which result agrees with the conclusions arrived at by American engineers on this subject.

This property of the metal is important in two respects. First, because inasmuch as the extension per ton per inch is practically equal to the compression, it follows that the neutral axis of a structure of steel, strained transversely, will be in the centre of gravity of its section, and that the proper proportion to give to the upper and lower flanges of a girder, when made of the same quality of steel throughout, will be the same as in wrought-iron. Secondly, because the modulus of elasticity of steel is practically equal to that of wrought-iron, and the limit of elasticity is greater, it follows that in a girder of the same proportions as wrought-iron, and strained with an equal proportion of its ultimate tensile strength, the deflection will be greater in the steel than in the iron girder, in the rate of the strength of the metals; so that if it is necessary to make a steel girder for a given span deflect under its load the same amount as an iron girder of the same span, the steel girder must be made of greater depth.

The fourth series of experiments were made by the Committee on riveted steel, and show clearly that the same rules which

apply to the riveting of iron apply equally to steel; that is to say, that the total shearing area of the rivets must be the same, or rather must not be less, than the sectional area of the bar riveted. . . .

We know from established mechanical laws that the limiting spans of structures vary directly as the strength of the material employed in their construction when the proportion of depth to span and all other circumstances remain the same. We know also that, taking an ordinary form of open wrought-iron detached girder (as, for example, when the depth is one-fourteenth of the span), the limiting span in iron, with a strain of 5 tons to the inch upon the metal, is about 600 ft.; and it follows that a steel girder of like proportions, capable of bearing 8 tons to the inch, would have theoretically a limiting span of 960 ft.

This theoretical limiting span of 960 ft. would, however, be reduced by some practical considerations connected with the minimum thickness of metal employed in certain parts, and it would, in effect, become about 900 ft. for a girder of the before-mentioned construction and proportions.

The knowledge of the limiting span of a structure, as has been explained elsewhere, enables us to estimate very quickly, and with close approximation to the truth, the weight of girders required to carry given loads over given spans; and although the limiting spans vary with every form of structure, we can obtain an idea of the effect of introducing steel by the relative weights of steel and iron required in girders of the kind above mentioned.

Assuming a load in addition to the weight of the girder of one ton to the foot, the relative weights under these conditions would be as follows:—

Span.	Weight of steel girder. tons.	Weight of iron girder. tons
200	57	100
300	150	300
400	320	800

It is not alone in the relative weight or in the relative cost that the advantage of the stronger material is important, but with steel we shall be enabled to cross openings which are absolutely impracticable in iron.

It will naturally be asked why it is that steel is not used in these structures, if such manifest advantages would result from its employment.

The reason is twofold:—

1st. There is a want of confidence as to the reliability of steel in regard to its toughness and its power to resist fracture from sudden strain.

2nd. Steel is produced of various qualities, and we do not possess the means, without elaborate testing, of knowing whether the article presented to us is of the required quality for structural purposes. A third reason, arising probably out of those before mentioned, is found in the fact that in the regulations of the Board of Trade relative to railway structures, although rules are given for the employment of cast-iron and wrought-iron, steel has not, up to the present time, been recognised or provided for.

Now, as regards the question of toughness and malleability, and referring again to Mr. Kirkaldy's experiments, it appears that in the tests of "Bessemer steel" 18 samples were tried under tensile strain, the length of the samples being in round numbers 50 in. and the diameter 1·382 in.; and that when these were subjected to ultimate strain, the elongation at the moment of fracture was in the most brittle example 2¾ in., but generally varied from 4½ to 9½ inches.

In the experiments on transverse strain, in which the bars were nearly 2 in. square and only 20 in. between the points of support, all the "Bessemer steel" samples, except two, bent 6 in. without any crack. Again, in the experiments made by the Committee on bars 14 ft. long and 1½ in. in diameter, out of 20 bars of the milder quality of steel, 16 extended more than 8 in., and of these 10 extended more than 12 in. . . .

The treatment by comparison is especially important where metal is required in large masses and of great ductility because the larger the mass and the greater the ductility, the larger and more numerous are the air-cells, and the effect of the pressure is to completely close these cells and render the metal perfectly solid.

By this process mild steel can be made with a strength of 40 tons to the inch, having a degree of ductility equal to that of the best iron.

The more highly carbonised qualities show a decrease of ductility somewhat in the same ratio as the strength increases.

Without going into the numerous achievements of Sir Joseph Whitworth, resulting from the employment of steel, in connection with the extreme accuracy of workmanship produced at his works, or doing more than mention the flat-ended steel shot and shell which pass through iron plates when fired obliquely or penetrate ships' sides below the level of the water, I would call attention to those applications of steel which bear upon its strength and toughness.

In the first place, there are small arms made entirely of steel, of wonderful range and accuracy, capable of penetrating 34 half-inch planks, which is about three times the penetrating power of the Enfield rifle.

Secondly, there are the large guns, also entirely of steel, throwing projectiles from 250 lbs. to 310 lbs. in weight, and burning from 40 to 50 lbs. of powder at a charge, with which a range of nearly 6½ miles is obtained.

In both these cases the degree of strength and toughness required in the metal is much greater than is necessary for engineering structures.

It is unnecessary to occupy more time in multiplying examples of the toughness of steel. It is well known to manufacturers, and must also be well known to many others here present, that steel of the strength of 33 or 36 tons per inch can be made, and is made in large quantities at moderate price, possessing all the toughness and malleability required in engineering structures.

I will proceed, therefore, to the second part of the subject —namely, the want of means of knowing that a given sample of steel is of the quality suited for structural purposes.

With most other metals chemical analysis is in itself a complete and sufficient test of quality, but in steel it is not so. The toughness of steel may be altered by sudden cooling; and although the effect of this operation, and generally the effects of tempering, are greater when the quantity of carbon is considerable, yet it acts more or less in the mild qualities of steel; so that we cannot rely entirely on the aid of the chemist, but must fall back on mechanical tests. And in point of fact, seeing that the qualities required are mechanical, it is no more than reasonable that the test should be mechanical; for this includes not only the test of material but of workmanship.

Now there are two descriptions of mechanical testing, which may be distinguished as destructive and non-destructive—the one being beyond and the other within the elastic limit of the material. The destructive test is that usually applied to a part of an article manufactured, as, for example, a piece cut off a boiler plate and tested by absolute rupture, or by bending or otherwise, whereby the strength and quality of the material in the plate is known.

The non-destructive test is that usually applied to the finished work, as in the test of a boiler by hydraulic pressure, or the testing of a gun by the proof-charge. The strain in this case is made greater than that which will arise in the daily use of the article, but is not so greatly in excess as to be beyond the elastic limit of the material.

As regards engineering structures, this second test is easy of application; but it affords no sufficient criterion that the metal possesses that degree of toughness necessary to resist the action of sudden strains.

It may be said that engineers may ascertain for themselves, by inspection and testing at the works, that they are being supplied with the material that they require; but assuming that the tests and mode of testing were in all respects satisfactory to them, and that the metal supplied was of the right quality, we have still to comply with the conditions of the Act for the Regulation of Railways, and we must satisfy the Government Inspector.

It is not to be supposed that he can attend all the required tests at the works; and the question remains, how is the Inspecting Officer of the Board of Trade to be enabled to distinguish the quality of metal in a finished bridge, when he is called upon to give a certificate that it is safe for public traffic?

If we could adduce clear and distinct evidence that the metal used for a bridge was of a quality which would bear 8 tons to the inch with as much safety as common iron can bear 5 tons, there can be no reasonable doubt that the Board of Trade would make suitable provision in its regulations for the employment of such material.

The difficulty lies in the want of something whereby the quality of the metal may be known and relied upon with confidence by others besides those who made the article.

In gold and silver this is accomplished by the stamp put upon

them, in guns and small arms we have the proof-mark, but in iron and steel we have nothing whereby the one quality of metal can be distinguished from another; and until some sufficient means be devised for this purpose, it is difficult to see how we are to escape from the position in which we are now placed—namely, that while we possess a material by which we can increase considerably the spans and diminish the weight and cost of engineering works, we are restricted to make designs and construct our works by a rule made for wrought iron, and adapted to the lowest quality of that material.

As the rule made by the Board of Trade in respect of wrought-iron railway structures may not be generally known, I here give it :—

"In a wrought-iron bridge the greatest load which can be brought upon it, added to the weight of the superstructure, should not produce a greater strain on any part of the material than 5 tons per inch."

It will be observed that this 5 tons per inch is the governing element, irrespective entirely of the quality of metal used; and it is obvious that a rule so framed must act as a discouragement to any endeavour to improve the quality of metal, while it tends to induce the employment of the cheapest and most inferior descriptions which can be made under the name of wrought-iron.

In endeavouring to seek an amendment of the rules, which will permit of the employment of steel or other metal of higher strength than 5 tons to the inch, I feel bound to say that I do not consider that the Board of Trade is alone responsible for the position in which the question now stands; and as regards the Government Inspecting Officers, I can only say that in the numerous transactions I have had with them, and although differences of opinion have occasionally arisen, yet, considering the responsibility which rests upon them, I have found them anxious to afford all reasonable facilities so far as their instructions permitted.

The first step to be taken is to put our testing on a systematic and satisfactory basis.

The second is to establish some means whereby metal which has been tested can have its quality indicated upon it in such manner that it can be practically relied upon.

The experiments before referred to establish, sufficiently for all practical purposes, that the relation or proportion between the resistances to tension, compression, torsion, and transverse strain, is about the same in steel as in wrought-iron.

The testing required is therefore reduced to that necessary for ascertaining two properties, namely the strength and the toughness or ductility.

The strength may be readily ascertained, and no difficulty arises on that head.

The whole question turns upon the test for ductility, or the resistance to fracture by blows or sudden strain; and it must be admitted that the tests employed for this purpose are not framed on any regular or satisfactory basis.

Without, however, attempting to say what description of test may be found the best for ascertaining the property of ductility, it may be observed that what is required for this test is a definite basis to act upon, and that the samples should be so made as to render the test cheap, expeditious, and easy of application.

The next requirement is that when a piece of metal has been tested, and its qualities of strength and toughness ascertained, there should be some means of denoting its quality in an authentic manner.

To a certain extent this is already done in iron by the mark of the maker; but something more than this is necessary to fulfil the required conditions in steel.

What is termed steel, is iron with a small proportion of carbon in it. These two ingredients are necessary to constitute steel; and there may or may not be present in very small quantities graphite, silicon, manganese, sulphur, and phosphorus.

In connection with the experiments made by the Committee, fourteen of the samples were tested by Mr. E. Richards, of the Barrow Steel Works, five of which were kindly repeated by Dr. Odling.

Although there are some discrepancies in the results which we cannot account for, yet some of the characteristics are brought out clearly.

It appears that manganese may be present to the extent of four-tenths per cent. without injury either to the strength or ductility, but sulphur and phosphorus, except in extremely small quantities, are fatal to ductility.

In the samples tried by the Committee and Mr. Kirkaldy, the quantity of carbon varied from ¼ per cent. to nearly 1 per cent.; yet with this small variation in the carbon the strength ranged from thirty-three tons to nearly fifty-three tons per in.: and the ductility, represented by the ratio which the fractured area bore to the original section of the bar, varied from five-tenths in the tough qualities, until in the harder samples there was no diminution perceptible.

All these materials are called steel, and have the same external appearance; but possessing, as they do, such a range of strength and such a variation in ductility, it becomes absolutely essential that there should be some classification or means of knowing the respective qualities among them.

The want of such classification casts an air of uncertainty over the whole question of steel, and impedes its application. To this want of knowledge is to be ascribed the circumstance that many professional men regard the material as altogether unreliable; while large consumers of steel, in consequence of the uncertainty of the quality they buy in the market, seek to establish works on their own premises and make their own steel.

I ought, I know, to apologise for detaining you so long on this one question of steel, but I consider that the difficulties under which it is placed are affecting interests of considerable importance.

Not only is a large and useful field for the employment of steel practically closed, but the progress of improvement in engineering structures is impeded both in this country and in other parts of the world where English engineers are engaged.

For in consequence of the impediments to its employment in England, very few English engineers turn their attention to the use of steel. They are accustomed to make their designs for iron, and when engaged in works abroad where the Board of Trade rules do not apply, they continue for the most part to send out the old-fashioned ponderous girders of common iron, in cases where the freight and difficulties of carriage make it extremely desirable that structures of less weight and more easy transport should be employed.

In conclusion, and while thanking you for the patience with which you have heard me on this subject, I would observe that we possess in steel a material which has been proved, by the numerous uses to which it is applied, to be of great capability and value: we know that it is used for structural purposes in other countries, as, for example, in the Illinois and St. Louis Bridge in America, a bridge of three arches, each 500 ft. span; yet in this country, where "modern steel" has originated and has been brought to its present state of perfection, we are obstructed by some deficiency in our arrangements, and by the absence of suitable regulations by the Board of Trade, from making use of it in engineering works.

And I have considered it right to draw your attention to the position in which this question stands, well knowing that I could not address any body of gentlemen more capable of improving and systematising our methods of testing, or better able to devise effectual means for removing the impediments to the use of steel, than are to be found in the scientific and practical men who form the Mechanical Section of the British Association.

AFRICAN TRAVEL

The Lands of Cazembe. Lacerda's Journey to Cazembé in 1798. Translated and annotated by Captain R. F. Burton, F.R.G.S.; also, Journey of the Pombeiros, P. J. Baptista and Amaro José across Africa from Angola to Tette on the Zambize. Translated by B. A. Beadle; and a *Résumé* of the Journey of MM. Monteiro and Gamitto. By Dr. C. T. Beke. (Published by the Royal Geographical Society; John Murray, 1873.)

The African Sketch Book. By Winwood Reade, with maps and illustrations, in two volumes. (Smith, Elder and Co., 1873.)

THESE are extremely different kinds of books, though both are valuable. The first is almost unreadable except by geographical students; the second is thoroughly popular and amusing. The pending explorations of Livingstone have given a special interest to the various journeys of Portuguese explorers, and the Royal Geographical Society have done well in making the records of these journeys accessible to English readers. The earliest and most important is that of Dr. De Lacerda, who went on a Government mission to the capital of Cazembé, situated at the southern extremity of Lake Moero, about 500 miles north-west of Lake Nyassa. He died on the way, but the journey was concluded under the second in command. The Journal is given at length, and is very dull reading, except for the insight it gives into the character of the numerous Portuguese and half-castes who accompanied the expedition, and who were in a continual state of squabble from the first day to the last. Dr. De Lacerda was evidently an amiable and intelligent man, and his notes are comparatively pleasant reading, and give some little notion of the country and the people. The Journal of his successor, an ecclesiastic (Fr. Pinto), is, however, so exclusively occupied with a record of the disputes among the members of the expedition, that it was hardly worth printing. Capt. Burton's translation is very free, and no doubt very accurate, but he is so idiomatic as almost to require translating himself; and such terms as "loot," "dash," "notions," and "magotty heads," which are repeatedly used, are hardly characteristic of the serious and matter-of-fact diary of the Portuguese explorers. His notes are very copious, often considerably exceeding the text, and some of them are instructive; but we find in them too many onslaughts on Mr. Cooley, and endless minute criticisms on African orthography. The free statement of Capt. Burton's peculiar views on civilisation, religion, polygamy, and other matters, is also rather out of place. We are told for instance that, to Capt. Burton, "Alexander is the first person of the triad which humanity has as yet produced; the other two being Julius Cæsar and Napoleon Bonaparte," and that "Blakeley guns and railways" are the indices of true progress.

If, however, this part of the book is dull, the second part—the Route Journal of the Pombeiros—is dreary in the extreme. We have page after page of such entries as these:—"Friday, 12th—At seven in the morning we got up and left the top of the hill. We passed seven narrow streams which run into the Luapula. We came to another desert near a narrow river where we found a circle made. We met nobody and walked with the sun in our front." In the third part we are spared the detailed journals and are given a *résumé* by Dr. Beke, in which we have all that is of interest compressed into a few pages. These journals show that African travel was beset with the same difficulties and troubles seventy years ago as it is now, and that the custom of exacting presents and causing delays at every village is an ancient African institution. The work is illustrated by an excellent map, in which all the geographical information to be extracted from these journeys is laid down, and the routes of all the travellers, as well as those of Livingstone, distinctly marked. It will therefore be of great value in tracing the future progress of that illustrious traveller.

Mr. Winwood Reade's well-named "African Sketch Book" is a work of an altogether novel kind. In a series of picturesque and sparkling chapters he gives us sketches of the various pictures of African life and scenery, episodes of travel, the slave trade, the history of African exploration, and other subjects; and interspersed with these are little tales illustrative of the various phases of native life or of European life in Africa. Mr. Reade has twice visited Africa. The first time, in 1862-63, he went over Du Chaillu's ground, and enabled us to separate the true from the imaginative in that traveller's book; and he also visited Angola and Senegambia. The second time, in 1868—70, he spent two years in Africa, on the Gold Coast and Liberia, and made an adventurous journey from Sierra Leone to the Niger, at a point never before reached by a European traveller. The narrative of this journey occupies about half the second volume, and is very interesting; although it is perhaps a little marred by the sketchy style in which it is written (in the form of letters to a young lady), and by the prominence given to the author's fears, hopes, and ambitions, all of which will, however, prove attractive to many readers. When within about fifty miles of the Niger, at Falaba, the traveller was stopped by a native king, Sewa, who kept him in his court, as Speke was kept, for several months, and then allowed him to return to Sierra Leone, sending with him an embassy and his own nephew, as an escort. Mr. Reade then endeavoured to get the Governor of Sierra Leone to send him on an expedition to the Niger, in which case Sewa would not have dared to stop him; but finding that there would be great delays before this could be arranged, he took the bold resolution, although seriously ill, to return at once with the king's nephew He did so, and telling the king, who was greatly surprised to see him, that he was now a traveller going to the Niger, but would stay with him three days, he was allowed to go on, and not only succeeded in reaching the Niger at a point about forty miles from its source, but went down its course to the north-east to the Bouré gold works, never before visited by any European. This journey undoubtedly stamps Mr. Reade as a thorough African explorer.

The six years' interval between his two journeys was devoted to a study of the literature of African travel, some of the results of which are embodied in a large and very useful map, showing at a glance the portion of the country visited by each traveller, as well as the various authorities which may be consulted on each district; and the comparative importance of these is indicated by the type in

which the name is printed. The chapter entitled "The African Pioneers," is a very interesting one, giving a spirited sketch of the life and labours of each of the important African travellers from Ledyard to Livingstone; and we think Mr. Reade could do no better or more popular work than to give us in a compact and readable form, and as much as possible in each author's own words, the concentrated essence of those vast piles of volumes on Africa, which he appears to have waded through.

There is a very great improvement in this work over Mr. Reade's earlier writings, and he himself recognises that his opinions are now changed for fairer and truer ones. He now speaks of the Negro race with respect, and often uses the term "native gentleman." He believes that "if boys were removed at an early age from uncivilised society and brought up with the sons of gentlemen at home, they would acquire something better than book-learning—namely the sentiment of honour. My long and varied experience of the African Race has brought me to believe that they can be made white men in all that is more than skin-deep." He speaks well of the native Missionaries, and says of one of them at Sierra Leone, of whom he saw a good deal, that he "does not differ, so far as I can see, from an English gentleman and clergyman in manners, speech, or disposition." Such men have far more influence with the natives than English clergymen can have. "An ordained Negro is a walking sermon, a theological advertisement. The savages regard an Oxford Master of Arts as a being fearfully and wonderfully made, belonging to a different species from himself. His argument invariably is, 'White man's God, he good for white man; black man's God, he good for black man.' But when he beholds a man as black as himself with a shiny hat, a white cravat, glossy garments, and shoes a yard long, wearing a gold watch in his fob, blowing his nose in a cloth, and 'making leaves speak;' and when he is informed that these are the results of being baptised, he also aspires to become a white man, and allows himself to be converted."

Good service is done by pointing out that what is usually called the typical Negro with jet-black skin, thick lips, and flat nose, is by no means typical, but is an extreme and exceptional type; that coffee colour of various shapes is the characteristic colour of Negroes, that their features are often finely formed, and of quite a European cast. Blackness of skin is said to be most prevalent where heat and moisture are combined, but it is recognised that this is not necessarily, or even probably, the cause of the blackness.

Mr. Reade's book is full of brilliant or witty sayings. Of the gorilla he says that "there is little doubt that some day or other this renowned ape will make its appearance at the Zoological Gardens, to brighten the holiday of the artisan, and to alleviate the sabbath of the fashionable world." Relating how a man once refused to guide him to a plantation about three miles off, for fear he should kill some game on the way and compel him to carry it, he remarks, "And yet it is often asserted that the Negroes are incapable of foresight." The natives of the interior firmly believe that Europeans buy slaves to eat, and an old cannibal Fan was anxious to know why they took the trouble to send so far for people to eat. Were the black men nicer than the white men? Mr. Reade's answer was dictated by motives of policy, as he was in a cannibal country. He assured his questioner that white men's flesh was a deadly poison, and so they were obliged to import their supplies! Of Livingstone it is remarked that "only twice in his life since he was a youth has he visited England, returning after a while to his true home in the wilderness, with his health shattered by the toils of literary composition."

We find also many passages of good or of doubtful philosophy. Mr. Reade seems impressed with the strange idea that if we could by any means double the number of our tall chimneys in the cotton districts, we should necessarily advance our civilisation and benefit the human race. For example, among arguments for opening up the Niger we are told:—"The country which lies beyond the confluence of the Quorra and the Binué is one of the largest cotton-growing areas of the world. At present the people dress themselves. But when the Niger trade is once established, our cheap cotton goods will soon destroy the native industry, and the people will export their raw cotton instead of weaving it themselves." And as one of the main results of the blood and treasure expended on African soil, we are told that "new markets have been opened for British manufactures." But does it not occur to Mr. Reade, that to destroy native industries instead of improving them may not advance a people; and that to increase the already large proportion of our population who pass their lives in a monotonous routine amid the smoke of furnaces and the din of machinery, and helpless as infants if their own source of living fails them (as it has failed them and may again), may not really advance us on the road to civilisation?

As an example of the manner in which our author often compresses into a few lines the results of much labour, take the following passage summarising the results of Nile exploration and the relative share of the two great branches in forming the River Nile and the Land of Egypt:—"Thus the Nile is created by the rainfall of the Equator, and Egypt by the rainfall of the Tropics. If the White Nile did not exist, the Black Nile would be nothing—it would perish in the sand. But if the Black Nile did not exist, the White Nile would be merely a barren river in a sandy plain, with some Arab encampments on its banks."

The arrangement of this book seems to be its weakest point. We are taken up and down the coast, and back again over old ground, till we hardly know where we are; and the confusion is increased by the insertion of the illustrative tales in the body of the work. It would have been far better if these tales had been kept together, and the rest of the work arranged in systematic geographical order. The work is provided with numerous good woodcuts; and the maps, which illustrate in a novel and ingenious manner the slave trade, the religions of Africa, African discovery, and African literature, are very valuable. The tales themselves are clever, and some admirably illustrative of African life; but most of them are melancholy in their catastrophes, and indicate that the author takes a somewhat gloomy view of human life and human nature. Of these, "Ananga" is the best. It is the story of a daughter of the King of Cazembé, who marries a Portuguese officer and runs away with him; and, arriving in the Cape Colony, is so overwhelmed by

the rush of new ideas excited by one after another of the wonders of civilisation, that she dies, like the Lady of Burleigh, overcome

"By the burthen of an honour unto which she was not born."

It is altogether a charming story, and is written in a style which we hope Mr. Reade will cultivate.

In justice to the author, it must be stated that the present work is intended for family reading, and to popularise a knowledge of modern Africa. He promises a more serious book, treating of many subjects in connection with the native races, of great interest to students of man; and this will be looked forward to with interest, since few men are now better qualified than Mr. Reade, both by travel and study, to tell us the real truth about the Negro. ALFRED R. WALLACE

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

Tait and Tyndall

[WE have received further communications from Professors Tyndall and Tait on the subject of the correspondence that has appeared in our columns. We feel that we are only consulting the true interests of Science in declining to print further communications on a subject which has assumed somewhat of a personal tone, and in this idea we are supported by many of the best friends of both parties, who, however, will approve of our giving the following brief extract from Dr. Tyndall's communication:—"My letter was rapidly written, and the proof of it reached me, not on the Tuesday evening, as I expected, but on the Wednesday morning when I was in the midst of my preparations for Bradford. I had therefore little time to give it the calm thought which it ought to have received. On re-reading it I find two passages in it which I think it desirable to cancel. The first is that in which I speak of lowering myself to the level of Prof. Tait; the second that in which I reflect upon his manhood. These passages I wish to retract."—ED. NATURE]

On the Males and Complemental Males of certain Cirripedes, and on Rudimentary Structures.

I BEG permission to make a few remarks bearing on Prof. Wyville Thomson's interesting account of the rudimentary males of *Scalpellum regium*, in your number of August 28th. Since I described in 1851, the males and complemental males of certain cirripedes, I have been most anxious that some competent naturalist should re-examine them; more especially as a German, without apparently having taken the trouble to look at any specimens, has spoken of my description as a fantastic dream. That the males of an animal should be attached to the female, should be very much smaller than, and differ greatly in structure from her, is nothing new or strange. Nevertheless, the difference between the males and the hermaphrodites of *Scalpellum vulgare* is so great, that when I first roughly dissected the former, even the suspicion that they belonged to the class of cirripedes did not cross my mind. These males are half as large as the head of a small pin; whereas the hermaphrodites are from an inch to an inch and a quarter in length. They consist of little more than a mere sack, containing the male reproductive organs, with rudiments of only four of the valves; there is no mouth or alimentary canal, but there exists a rudimentary thorax with rudimentary cirri, and these apparently serve to protect the orifice of the sack from the intrusion of enemies. The males of Alcippe and Cryptophialus are even more rudimentary; of the seventeen segments which ought to be fully developed, together with their appendages, only three remain, and these are imperfectly developed; the other fourteen segments are represented by a mere slight projection bearing the probosci-formed penis. This latter organ, on the other hand, is so enormously developed in Cryptophialus, that when fully extended it must have been between eight and nine times the length of the animal! There is another curious point about these little males, viz., the great difference between those belonging to the several species of the same genus Scalpellum: some are manifestly pedunculated cirripedes, differing by characters which in an independent creature would be considered as of only generic value; whereas others do not offer a single character by which they can be recognised as cirripedes, with the exception of the cast-off prehensile, larval antennæ, preserved by being buried in the natural cement at the point of attachment. But the fact which has interested me most is the existence of what I have called Complemental Males, from their being attached not to females, but to hermaphrodites; the latter having male organs perfect, although not so largely developed as in ordinary cirripedes. We must turn to the vegetable kingdom for anything analogous to this; for, as is well known, certain plants present hermaphrodite and male individuals, the latter aiding in the cross-fertilisation of the former. The males and complemental males in some of the species of three out of the four very distinct genera in which I have described their occurrence, are, as already stated, extremely minute, and, as they cannot feed, are short-lived. They are developed like other cirripedes, from larvæ, furnished with well-developed natatory legs, eyes of great size and complex prehensile antennæ; by these organs they are enabled to find, cling to, and ultimately to become cemented to the hermaphrodite or female. The male larvæ, after casting their skins and being as fully developed as they ever will be, perform their masculine function, and then perish. At the next breeding season they are succeeded by a fresh crop of these annual males. In *Scalpellum vulgare* I have found as many as ten males attached to the orifice of the sack of a single hermaphrodite; and in Alcippe, fourteen males attached to a single female.

He who admits the principle of evolution will naturally inquire why and how these minute rudimentary males, and especially the complemental males, have been developed. It is of course impossible to give any definite answer, but a few remarks may be hazarded on this subject. In my "Variation under Domestication," I have given reasons for the belief that it is an extremely general, though apparently not quite universal law, that organisms occasionally intercross, and that great benefit is derived therefrom. I have been laboriously experimenting on this subject for the last six or seven years, and I may add, that with plants there cannot be the least doubt that great vigour is thus gained; and the results indicate that the good depends on the crossed individuals having been exposed to slightly different conditions of life. Now as cirripedes are always attached to some object, and as they are commonly hermaphrodites, their intercrossing appears, at first sight, impossible, except by the chance carriage of the spermatic fluid by the currents of the sea, like pollen by the wind; but it is not probable that this can often happen, as the act of impregnation takes place within the well-enclosed sack. As, however, these animals possess a probosci-formed penis capable of great elongation, two closely attached hermaphrodites could reciprocally fertilise each other This, as I have elsewhere proved, does sometimes, perhaps often, actually occur. Hence perhaps it arises, that most cirripedes are attached in clusters. The curious Anelasma, which lives buried in the skin of sharks in the northern seas, is said always to live in pairs. Whilst reflecting how far cirripedes

usually adhered to their support in clusters, the case of the genus Acasta occurred to me, in which all the species are embedded in sponges, generally at some little distance from each other; I then turned to my description of the animal, and found it stated, that in several of the species the probosci-formed penis is "remarkably long;" and this I think can hardly be an accidental coincidence. With respect to the habits of the genera which are provided with true males or complemental males:—all the species of Scalpellum, excepting one, are specially modified for attachment to the delicate branches of corallines: the one species of Ibla, about which I know anything, lives attached, generally two or three together, to the peduncle of another cirripede, viz. a Pollicipes: Alcippe and Cryptophialus are embedded in small cavities which they excavate in shells. No doubt in all these cases two or more full-grown individuals might become attached close together to the same support; and this sometimes occurs with *Scalpellum vulgare*, but the individuals in such groups are apt to be distorted and to have their peduncles twisted. There would be much difficulty in two or more individuals of Alcippe and Cryptophialus living embedded in the same cavity. Moreover, it might well happen that sufficient food would not be brought by the currents of the sea to several individuals of these species living close together. Nevertheless in all these cases it would be a manifest advantage to the species, if two individuals could live and flourish close together, so as occasionally to intercross. Now if certain individuals were reduced in size and transmitted this character, they could readily be attached to the other and larger individuals; and as the process of reduction was continued, the smaller individuals would be enabled to adhere closer and closer to the orifice of the sack, or, as actually occurs with some species of Scalpellum and with Ibla, within the sack of the larger individual; and thus the act of fertilisation would be safely effected. It is generally admitted that a division of physiological labour is an advantage to all organisms; accordingly, a separation of the sexes would be so to cirripedes, that is if this could be effected with full security for the propagation of the species. How in any case a tendency to a separation of the sexes first arises, we do not know; but we can plainly see that if it occurred in the present case, the smaller individuals would almost necessarily become males, as there would be much less expenditure of organic matter in the production of the spermatic fluid than of ova. Indeed with *Scalpellum vulgare* the whole body of the male is smaller than a single one of the many ova produced by the hermaphrodite. The other and larger individuals would on the same principle either remain hermaphrodites, but with their masculine organs more or less reduced, or would be converted into females. At any rate, whether these views are correct or not, we see at the present time within the genus Scalpellum a graduated series: first on the masculine side, from an animal which is obviously a pedunculated cirripede with well-proportioned valves, to a mere sack enclosing the male organs, either with the merest rudiments of valves, or entirely destitute of them; and secondly on the feminine side, we have either true females, or hermaphrodites with the male organs perfect, yet greatly reduced.

With respect to the means by which so many of the most important organs in numerous animals and plants have been greatly reduced in size and rendered rudimentary, or have been quite obliterated, we may attribute much to the inherited effects of the disuse of parts. But this would not apply to certain parts, for instance to the calcareous valves of male cirripedes which cannot be said to be actively used. Before I read Mr. Mivart's acute criticisms on this subject, I thought that the principle of the economy of growth would account for the continued reduction and final obliteration of parts; and I still think, that during the earlier periods of reduction the process would be thus greatly aided. But if we consider, for instance, the rudimentary pistils or stamens of many plants, it seems incredible that the reduction and final obliteration of a minute papilla, formed of mere cellular tissue, could be of any service to the species. The following conjectural remarks are made solely in the hope of calling the attention of naturalists to this subject. It is known from the researches of Quetelet on the height of man, that the number of individuals who exceed the average height by a given quantity is the same as the number of those who are shorter than the average by the same quantity; so that men may be grouped symmetrically about the average with reference to their height. I may add, to make this clearer, that there exists the same number of men between three and four inches above the average height, as there are below it. So it is with the circumference of their chests; and we may presume that this is the usual law of variation in all the parts of every species under ordinary conditions of life. That almost every part of the body is capable of independent variation we have good reason to believe, for it is this which gives rise to the individual differences characteristic of all species. Now it does not seem improbable that with a species under unfavourable conditions, when, during many generations, or in certain areas, it is pressed for food and exists in scanty numbers, that all or most of its parts should tend to vary in a greater number of individuals towards diminution than towards increment of size; so that the grouping would be no longer symmetrical with reference to the average size of any organ under consideration. In this case the individuals which were born with parts diminished in size and efficiency, on which the welfare of the species depended, would be eliminated; those individuals alone surviving in the long run which possessed such parts of the proper size. But the survival of none would be affected by the greater or less diminution of parts already reduced in size and functionally useless. We have assumed that under the above stated unfavourable conditions a larger number of individuals are born with any particular part or organ diminished in size, than are born with it increased to the same relative degree; and as these individuals, having their already reduced and useless parts still more diminished by variation under poor conditions, would not be eliminated, they would intercross with the many individuals having the part of nearly average size, and with the few having it of increased size. The result of such intercrossing would be, in the course of time, the steady diminution and ultimate disappearance of all such useless parts. No doubt the process would take place with excessive slowness; but this result agrees perfectly with what we see in nature; for the number of forms possessing the merest traces of various organs is immense. I repeat that I have ventured to make these hypothetical remarks solely for the sake of calling attention to this subject.

CHARLES DARWIN

Down, Beckenham, Kent, Sept. 20

Reflection of the Rainbow

DRAW a circle to represent a rain-drop, or rather a section of it, by a plane passing through its centre, the sun, and the eye. Draw a straight line through the centre to represent a solar ray of mean refrangibility. At the front and back of the drop reflection occurs, and the incidence being normal, the incident and reflected beams will coincide after the emergence of the latter from the drop. Now suppose the ray through the centre to move parallel to itself, the incidence grows more and more oblique, refraction occurs at entrance and at emergence, the ray finally becoming a tangent to the drop. Let the incident and the twice refracted and once reflected rays be produced backwards till they intersect behind the drop: the angle enclosed between them augments with the obliquity, reaches a maximum, and then diminishes. The ray corresponding in obliquity with this maximum angular value, and those in its immediate vicinity, quit the drop sensibly parallel, and these are the rays which are effectual in the rainbow. This angle being for red light 42°, and for violet light 40°, for light of mean refrangibility it is 41°.

If those parallel rays before reaching the observer's eye impinge

upon a surface of calm water, they are, in part, reflected according to the usual law, and *a* rainbow is then seen by reflection. But the absolute position of the bow changes with every change in the position of the observer's eye; hence the bow seen mirrored in the pool is *not* the reflection of that seen at the same time directly in the heavens. Suppose the shower to be fixed in space, then the drops which produce the bow seen directly, would not be those which produce the bow as seen by reflection.

In the paragraph to which your correspondent "Z.X.Y." has called attention, I meant to combat the notion, entertained by many, that the rainbow is reflected after the fashion of an ordinary floating cloud which emits light in all directions, and which, by the light thus emitted, paints its image in the water. A few additional words might have made my meaning clearer; but as I was dealing at the time more with historic statement than with scientific exposition, I desired to be brief. I can hardly think, however, that your correspondent will be angry with me for giving him what must have been agreeable as well as successful occupation at the Falls of the Rhine.

Royal Institution, Sept. 15 JOHN TYNDALL

Original Research at the Universities

MY attention has been arrested by the following sentence in the extract given by you from Prof. Frankland's evidence before the Science Commission:—"I believe that one cause (of the slow progress of original research in England) lies in the entire non-recognition of original research by any of our Universities. Even the University of London, which has been foremost in advancing instruction in experimental science, gives its highest degree in Science without requiring any proof that the candidate possesses the faculty of original research, or is competent to extend the boundaries of the science in which he graduates."

It may interest Dr. Frankland and those who take the same view as he does, to know that this subject has engaged the attention of the graduates of the University of London. At a meeting of the Annual Committee of Convocation in December last, it was moved by Prof. Guthrie—

"That every candidate for the degree of Doctor of Science shall be required to submit to his respective Examiners a written dissertation embodying some original research in one or more of the subjects of his intended examination; and that such dissertation be approved before the candidate be allowed to proceed to examination."

This motion I had the honour of seconding; but the degree of acceptance which the principle involved in it met with from the Committee is seen by the sequel, as stated in the printed minutes, that it was "rejected by a large majority." The exact numbers, if my memory serves me rightly, were Ayes, 3; Noes, 16; among the Noes were two Doctors and one Bachelor of Science, and at least five Doctors of Medicine. The "Annual Committee," it may be stated, is a representative body elected annually by the graduates in Convocation, but has no legislative or administrative power, this resting entirely with the Senate.

ALFRED W. BENNETT

Endowment of Research

WITH regard to the Endowment of Scientific Research, could not this be well placed in the hands (as it now is, to a very limited extent) of a Committee of the British Association? the committee being authorised to supply funds for experimental purposes, and the members, say three or four in number, to have a permanent salary for the time spent in the examination of claims from applicants.

It might possibly be desirable that one or more of the committee should retire every two or three years and not be eligible for re-election until after the lapse of three years; and also, to prevent waste of time, that all applications for help should be presented only through one or more gentlemen of known scientific attainments, and not of necessity at the instigation of the person to whom the assistance was to be rendered. I believe that this would be a good practical arrangement as regards the poorer class, who are compelled to throw up valuable original researches to supply themselves and those depending on them with homes and food.

The abuse of a trust of this kind would hardly be possible, as the help would of necessity be given in those cases where a certain amount of work had already been done under difficulties, and where the natural instinct for original research was of necessity strongly developed. The presentation of an annual sum for, say five years, renewable at the end of the time if necessary, would be a godsend to many a man who has allowed himself to starve for the benefit of posterity.

THOS. FLETCHER

FERTILISATION OF FLOWERS BY INSECTS *

III.

On the co-existence of two forms of flowers in the same species or genus,—a more conspicuous one adapted to cross-fertilisation by insects, and a less conspicuous one adapted to self-fertilisation.

SINCE Darwin, in his admirable work on Orchids,† had proved that the flowers of this family are endowed with an immense variety of comtrivances for cross-fertilisation by insects, it was almost generally admitted by botanists that cross-fertilisation is the rule throughout the whole vegetable kingdom. Darwin's well-known aphorism, that "Nature abhors perpetual self-fertilisation" was exaggerated by his successors in this field of research, Hildebrand in Germany and Delpino in Italy, who, in their various elaborate memoirs on the fertilisation of flowers, repeatedly expressed their strong belief that nature abhors self-fertilisation at all. In direct opposition to this opinion, Axell ‡ propounded the doctrine that the development of the fertilising arrangements in phanerogams has been always an advance, and still continues to advance, in one and the same direction, towards a perfection which affords more and more facilities for self-fertilisation.

My own observations on the contrivances of our flowers and on the insects really visiting and fertilising them, have convinced me, that neither Hildebrand's and Delpino's, nor Axell's opinion is a thoroughly adequate one, but that under certain conditions the facility for self-fertilisation is most advantageous to a plant, while, under other conditions, the inevitableness of cross-fertilisation by the visits of insects is the more advantageous.

To all plants the flowers of which possess such a degree of attractiveness for insects that cross-fertilisation by these transporters of pollen is never wanting, the possibility of self-fertilisation is quite useless, and from this cause, not being subjected to the effects of natural selection, may be lost, like any useless peculiarity, and in many instances, indeed, has been lost. On the contrary, to those plants the flowers of which possess so slight a degree of attractiveness for insects, that the transportation of the pollen to the stigma by insects is effected in but very few cases, the possibility of self-fertilisation is most advantageous, and indeed we find in most cases such plants well adapted for self-fertilisation.

Among many facts which I could appeal to as proofs of my statements, there are, I believe, none more instructive than those alluded to in the superscription of this article.

In some species of our wild plants I have found on different plants two different forms of flowers, evidently showing the connection above stated between attractiveness for insects and adaptation for inter-crossing or for self-fertilisation. As nobody before, for aught I know, has observed this phenomenon, I will give some details of the most important instances hitherto observed.

Lysimachia vulgaris

Of this species specimens with more conspicuous flowers are found in sunny localities. The petals of this form are dark yellow with red at the base, on an average about 12 mm. long, and 6 mm. wide, opening widely and

* Continued from p. 206.

† "On the Various Contrivances by which British and Foreign Orchids are Fertilised by Insects." (London, 1863.)

‡ In his work: "Om anordningarna för fanerogama växternas befruktning." (Stockholm, 1869.)

bending outwards and backwards; the filaments are red-coloured towards their end; the style overtops the longest stamens by some millimetres. A species of bee, *Macropis labiata* Pz., frequently visits these flowers for pollen. It comes first into contact with the stigma, and supplies it with pollen from previously visited flowers, thus regularly effecting cross-fertilisation. But if we prevent the visits of insects by covering over the stems by a

FIG. 11.—Two anthers, seen from the inner side, showing the slits fringed with hairs.

net, self-fertilisation scarcely takes place, in consequence of the style overtopping all the stamens.

Specimens of the same species with less conspicuous flowers are found in shady ditches. The petals of these plants are lighter yellow, uniform in colour, without any red at the base, on an average 10 mm. long, and 5 mm. wide; they only open slightly, remaining nearly upright,

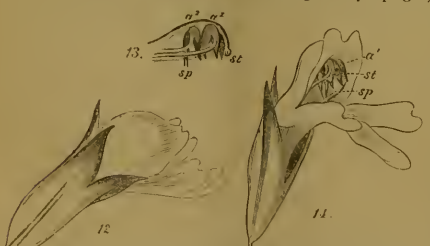

FIG. 12—Lateral view of a flower of the smallest form, just opening.
FIG. 13.—Position of the stigma (*st*) and the anthers (a^1, a^2) in this flower.
FIG. 14.—Front view of a flower of the same form, in a more advanced state.
(All the figures are magnified in the proportion of 7 : 1. The hairs of the calyx and the coloured spots and lines of the corolla are omitted.)

but diverging obliquely; the filaments are greenish yellow, without any red towards their end; the style hardly equals the two lowest and longest stamens. The stigma comes without any external agency into contact with the pollen of the same flower thus regularly experiencing self-fertilisation. This manner of producing seeds is an indispensable condition for preservation of this variety of *Lysimachia vulgaris.* For in consequence of its shady habitat, and of its lower degree of attractiveness for insects, its flowers are but very rarely visited, and it would be exposed to extinction without the possibility of propagation by self-fertilisation. I but once observed a little fly of the family of Syrphidæ, *Syritta pipiens* L., eating the pollen of this shady form of flowers. Although this fly might possibly transport pollen from one flower to the stigma of another, cross-fertilisation was nevertheless by no means more probable than self-fertilisation.

The two forms here described of the flowers of *Lysimachia vulgaris* graduate into each other by connecting forms, which are met with in intermediate localities, for instance on the sunny edges of ditches.

Another example of the same sort of dimorphism, even more striking than that just mentioned, is presented by *Euphrasia officinalis.* Of this species flowers are found in different localities of a very different size. But the more the attractiveness for insects is increased by the size of the corolla, the more is cross-fertilisation secured in case insects visit the flowers, self-fertilisation at the same time being prevented; while on the contrary, the smallest flowers regularly fertilise themselves, even without the visits of insects. I will attempt to explain these peculiarities by drawings of the largest and of the smallest form of flowers I have hitherto been able to find.

In the flower just opened of the largest form (as shown in Fig. 9), the stigma, already in a mature condition, greatly overtops the anthers. Therefore an insect,* inserting its proboscis into the tubular corolla in order to gain the nectar contained at the bottom of its tube, first grazes the stigma charging it with pollen-grains from flowers previously visited, and then pushes against the two hairs (*sp*) which project from the two lower anthers (a^2) into the middle of the entrance to the corolla. This shaking of the hairs is transmitted to all the four anthers, which lie close together and are soldered together by their upper margins, and a small quantity of the smooth powdery pollen-grains falls out of all the pollen sacs. The slits in the pollen sacs being fringed with hairs directed downwards (as shown in Fig 11) a lateral dispersion of the pollen-grains is prevented; all the pollen-grains shaken out fall directly downwards upon the proboscis, enabling it to fertilise the next flower visited by the insect.

In the state just described the corolla has not yet attained its full size. Growing farther, it at length equals the stigma by which it was at first so much overtopped, and now the mutual position of the stigma and the anthers is that shown in Fig. 10. When occupying this position, the stigma is always already shrivelled and brownish coloured, and is no longer capable of being fertilised. Self-fertilisation is therefore quite impossible.

The probability of cross-fertilisation and of self-fertilisation is directly opposite in the flowers of the smallest form, presented by Fig. 12—14. Whilst in the flowers of the largest form, as just described, the anthers remain soldered together, and do not scatter their pollen unless the hairs are shaken, in the flowers of the smallest form the anthers separate from each other, and scatter nearly all their pollen long before the corolla has fully opened. The end of the style, moreover, bends inwards so much as to bring the stigma (as Fig. 13 shows) close beneath the upper anthers. Therefore, on examining a flower hardly half-opened (Fig. 12), we always find the stigma already largely charged with pollen-grains of the same flower. When fully opened, the flowers of the smallest form show the stigma in a shrivelled and brownish coloured condition, lying between the separated and emptied pollen-sacs (as shown in Fig. 14). Hence cross-fertilisation could scarcely be effected, even if insects (which I never

* I observed four species of bees and three species of Diptera visiting the flowers of *Euphrasia officinalis* for honey.

observed) should visit these very inconspicuous flowers. The fringing hairs in the flowers of the largest form, so nicely securing the perpendicular falling of the pollen-grains upon the proboscis, are quite useless in a flower regularly restricted to self-fertilisation; indeed, in the anthers of the smallest form we find no fringing hairs at all, or only a few isolated ones.

The two extreme forms here described graduate into each other by various intermediate forms. When publishing my book on "Fertilisation of Flowers by Insects," I had never observed either the largest or the smallest form here described. From this cause the figures in page 291 of my work, drawn from other varieties, differ in some points from the description here given.

In *Lysimachia vulgaris* the two forms here described are so closely allied, that no botanist, for aught I know, has considered them worthy of being distinguished as varieties by separate names; in *Euphrasia officinalis* the difference between the two forms is somewhat greater, and some botanists, although overlooking the different manner of fertilisation, have distinguished them as varieties, (for instance, Ascherson in his "Flora der Provinz Brandenburg").

In a third example of the same dimorphism of flowers, presented by *Rhinanthus crista galli*, the divergence of the two forms has proceeded so far that most botanists distinguish them by separate names, some as varieties (*Rh. crista galli* α and β of Linnæus), others as distinct species (*Rh. major* Ehrh. and *Rh. minor* Ehrh). These two forms differ with respect to their fertilisation, nearly in the same manner as the largest and the smallest form of *Euphrasia officinalis*. *Rh. minor* having a smaller corolla, and therefore being but rarely visited by insects, regularly fertilises itself when insects do not visit it, by bending the stigma beneath the pollen-sac, which at last opens spontaneously, and covers the stigma with its pollen-grains. In *Rh. major* the stigma so far overtops the pollen-sac that self-fertilisation is excluded. It is, however, a remarkable difference between *Rh. minor* and the smallest form of *Euphrasia officinalis*, that the former is regularly cross-fertilised, when visited by insects, if this happens not too late, and that it only has recourse to self-fertilisation if altogether unvisited by insects.*

Lippstadt, Sept. 9 HERMANN MÜLLER

THE 'POLARIS' ARCTIC EXPEDITION

THE missing link in the story of the *Polaris* Expedition has been picked up, and the narrative, as a whole, is one of the strangest in the whole history of Arctic adventure. Our readers may remember the story we gave of the 19 persons who were left on the ice-floe when the *Polaris* broke from her moorings in about N. lat. 79°, on the night of October 19, 1872, and who were all miraculously rescued six months later off the coast of Labrador. Eleven more of the crew arrived at Dundee last Friday afternoon in the whaling vessel, *Arctic*, Capt. Adams. Among these eleven are, Capt. S. O. Buddington, sailing and ice master, Dr. Emil Bessels, H. C. Chester, first mate, W. Martin, second mate, Emil Schumann, chief engineer, A. Odell, second engineer, besides a fireman, the carpenter, and three seamen.

After the ship drifted away from the floe she ultimately reached Lifeboat Cove, where it was resolved to beach her, which was done after much trouble. From the timbers of the ship a house was constructed on shore, and by the help of a few friendly Esquimaux, and the provisions and coals saved from the *Polaris*, the fourteen men spent the winter much more comfortably than might have been expected under the circumstances. Towards the end of the winter, however, it was resolved to make an attempt to push southwards, and for this purpose under the superintendence of the energetic first mate, Mr. Chester, of whom all the crew speak in high terms, two boats were, amid many hardships, constructed out of some of the cabin-timbers of the *Polaris*. About the middle of last June, the boats having been completed and packed with what provision could be had, as well as ammunition, the party bade adieu to Lifeboat Cove and proceeded to make their way southwards. After many anxieties Cape York was reached on June 21. Here the boats were quite beset among the ice, but the greatest possible excitement and fear were experienced when, on the 23rd, a vessel was espied. She turned out to be the *Ravenscraig* whaler, of Dundee, Capt. Allan. All hands determined to reach the ship with the least possible delay, but in doing so they were greatly assisted by Capt. Allan, who had sent his crew to help them in carrying what things they had in their possession. They brought one boat with them and left the other. On reaching the ship they were very kindly treated, but subsequently, so that the fishing operations might be interrupted as little as possible, Capt. Allan shipped a few on the *Arctic*. The latter vessel having completed her fishing earlier than expected, and knowing that the crew of the *Polaris* would be anxious to return home as speedily as possible, Captain Adams, her commander, went in search of the *Ravenscraig*. Finding her, he took on board those of the survivors it contained, but Capt. Allan had previously put on board the *Intrepid*—R. W. D. Bryan, astronomer and chaplain; J. B. March, seaman; and John W. Booth, fireman. The *Intrepid* is expected in the course of a few weeks. The men state that the privations which they suffered were by no means of a serious character. The life was rough, laborious, and monotonous, and although danger occasionally presented itself in a way well calculated to inspire the greatest fear, yet no accident of any importance occurred to the adventurers.

Capt. Markham, R.N., accompanied Capt. Adams, of the *Arctic*, on his whaling voyage with the view of making investigations in the northern regions. The captain left Dundee on Friday, and was present in the Geographical Section at Bradford on Saturday, where he was received with great enthusiasm, and where he announced himself as heart and soul a convert to the Smith Sound route to the Pole.

The men connected with the *Polaris* Arctic expedition left Dundee on Monday, and Liverpool on Tuesday, for New York. All were in excellent health and spirits, and some of them say that they would have no objection to go on another such enterprise. Capt. Buddington states that Capt. Hall was buried in lat. 81·38 N., and long. 61·44 W. The vice-consul examined the crew of the *Polaris* on Monday, and transmitted their depositions to America, so that their statements may be extant should any accident befall themselves.

Dr. Bessel, who was the chief of the scientific party connected with the expedition, states that zoological, meteorological, botanical, and geological specimens were collected, but many of them were lost when the crew separated in October last. Careful and minute observations were also made, and after the explorers were picked up by the *Ravenscraig* they were continued. These surveys, of course, were not so exact as was to be desired, there being little convenience and very few instruments. The specimens taken on board the whalers are all preserved, and it is believed that, from a scientific point of view, they will be of very great value. The opinion of Dr. Bessel is that, had no accident occurred to the *Polaris*, the expedition would have been prosecuted. Regarding statements which had been made respecting the causes which led to the death of Captain Hall, he asserts that the captain was carried off by an attack of apoplexy. The doctor declines to enter into the question as to the management of the expedition after

* A further explanation of these two forms is given in my book "Die Befruchtung der Blumen durch Insekten," pp. 294-296.

the death of Capt. Hall, but there is every likelihood the matters involved will be made the subject of judicial inquiry in America.

Taking all the circumstances into account, it is astonishing that both divisions of the crew have escaped without the loss of an individual and with so comparatively little hardship. The complete narrative of the *Polaris* Expedition, with the important scientific results obtained, will be looked for with impatient interest.

NOTES

We regret exceedingly to announce that Prof. Donati, Director of the Astronomical Observatory in Florence, died of cholera on the 20th inst. at Vienna, where he had arrived only two days previously.

Dr. Nelaton, the eminent surgeon, died at Paris on the 21st inst. at the age of 66 years.

The death is also announced at Paris of M. Coste, the well-known naturalist and member of the French Institute, at the age of sixty-six. He first devoted himself chiefly to the study of comparative embryogeny, and his earlier works attracted so much attention that a special professorship was created for him at the College of France. Of late years he had chiefly applied himself to the science of the artificial production of fish, and it was on his recommendation that the Government in 1851 founded the breeding ponds at Huningen for stocking the Rhône with salmon and trout, and which in two years produced 600,000 young fry in that river. As inspector-general of fluvial and coast fisheries, he also made numerous experiments for the propagation of oysters, but the expectations which had been raised by his theories have not so far been realised by the results obtained. M. Coste was the author of numerous physiological works and reports to the Academy of Sciences.

Our list is not yet complete. Prof. Czermak, the eminent physiologist, died at Leipzic on Tuesday, the 16th inst.

By the death of Prof. Barker, M.D., the professorship of Experimental Physics in the Royal College of Science for Ireland, Dublin, has become vacant. The chair is in the gift of the Lords of the Committee of Council on Education, South Kensington. It is of the value of 200*l*. per annum, besides a share in the fees paid by the students.

Prof. Hughes Bennett, of Edinburgh, has been elected Corresponding Member of the National Academy of Medicine of France.

There will be an election at Magdalen College, Oxford, in October next, to a Fellowship in Natural Science, the holder of which will not be required to take holy orders. In the examination, which will be held in common with Merton College, preference will be given to proficiency in Biology, the College reserving to themselves the power of taking candidates in any other branch of Natural Science, if it shall seem expedient to do so. Candidates must have passed all the examinations required by the University of Oxford or the University of Cambridge for the degree of Bachelor of Arts, and must not be in possession of any ecclesiastical benefice, or of any property, Government pension, or office tenable for life or during good behaviour (not being an academical office within the University of Oxford), the clear annual value of which shall exceed 230*l*. They must also produce testimonials of their fitness to become Fellows of the College as a place of religion, learning, and education, and these must be sent to the president on or before Monday, September 29. Candidates for the Fellowship are required to call on the president on Monday, October 6, between the hours of 3 and 5, or 8 and 9 P.M. The examination will commence on the following day.

It seems that the projected balloon voyage from New York to Europe is not now likely to take place. An attempt was made to inflate the balloon on the 10th, but it failed, owing to a high wind. The attempt was renewed on the 12th, but a rent appeared and the operation was abandoned. Mr. Wise, the aëronaut, had foreseen this result, owing to the imperfect manner in which the balloon was constructed; and indeed from what has been stated, it would seem Science may be congratulated that an enterprise in which newspaper advertising had so much to do, has been thus liberated from the responsibility of having to answer for a much more serious disaster, which, we repeat, need not be risked at all so far as Science is concerned.

Mr. George Smith has just discovered the fragments of an ancient Assyrian Canon, from the Babylonian copy of which the much-contested Canon of Berosus was unquestionably derived. The importance of this relic to chronologists can scarcely be over-estimated, and it will form the substance of a paper shortly to be read before the Society of Biblical Archæology by its fortunate discoverer.

A French translation of Grisebach's "Vegetation der Erde nach ihrer klimatischen Anordnung" is promised, with annotations, by M. P. de Tchihatchef.

We understand that Messrs. Macmillan will publish, early in the approaching season, a splendid series of pictures by Mr. Joseph Wolf, illustrative of the "Life and Habits of Wild Animals." The illustrations have been in course of engraving by Messrs. Whymper during the last seven years, and, as they are the last series which will be drawn by Mr. Wolf, either upon wood or upon stone, they will have an especial claim to the attention of all those who are interested in Natural History. The pictures are accompanied by descriptive letterpress by Mr. D. G. Elliot, whose monograph of the pheasants was noticed by us some time ago.

The *Journal of Botany* states that Dr. Beccari, the Italian traveller and collector, when last heard of, was at the island of Wokam, off the south-west coast of New Guinea; he was to go on to Amboina, and had made large collections of plants and animals, which no doubt will include a number of novelties.

The *Revue Horticole* states that M. Planchon, the Professor of Botany at Montpellier, has been charged by the French Government with the duty of visiting America to study the ravages of the new vine disease, the *Pemphigus vitifolia*. No change of government seems to lessen the sense of importance of scientific investigation displayed by our neighbours across the Channel.

A tract of hematite iron ore has been discovered in Shropshire, and eleven hundred acres have been secured on behalf of certain Staffordshire ironmasters, who will work it as a company. Some specimens contain 57 per cent. of iron. The discovery is of great importance to the iron industry.

The additions to the Zoological Society's Gardens during the past week include two Indian Antelopes (*Antilope cervicapra*) from India, presented by Mr. G. E. Rogers; an Alligator (*Alligator mississippiensis*) from America, presented by Dr. Palin; a Cardinal Grosbeak (*Cardinalis virginianus*), a Red-shouldered Starling (*Agelaeus pheniceus*), a Baltimore Hangnest (*Icterus baltimore*), from North America, presented by Mr. Samuel Stubbs; a Cuckoo (*Cuculus canorus*), British, presented by Dr. Williams; a Rattlesnake (*Crotalus durissus*) from North America, purchased; twelve White-faced Tree Ducks (*Dendrocygna autumnalis*) from Brazil; a Manx Shearwater (*Puffinus anglorum*), British, deposited.

MOLECULES*

An atom is a body which cannot be cut in two. A molecule is the smallest possible portion of a particular substance. No one has ever seen or handled a single molecule. Molecular science, therefore, is one of those branches of study which deal with things invisible and imperceptible by our senses, and which cannot be subjected to direct experiment.

The mind of man has perplexed itself with many hard questions. Is space infinite, and if so in what sense? Is the material world infinite in extent, and are all places within that extent equally full of matter? Do atoms exist, or is matter infinitely divisible?

The discussion of questions of this kind has been going on ever since men began to reason, and to each of us, as soon as we obtain the use of our faculties, the same old questions arise as fresh as ever. They form as essential a part of the science of the nineteenth century of our era, as of that of the fifth century before it.

We do not know much about the science organisation of Thrace twenty-two centuries ago, or of the machinery then employed for diffusing an interest in physical research. There were men, however, in those days, who devoted their lives to the pursuit of knowledge with an ardour worthy of the most distinguished members of the British Association; and the lectures in which Democritus explained the atomic theory to his fellow-citizens of Abdera realised, not in golden opinions only, but in golden talents, a sum hardly equalled even in America.

To another very eminent philosopher, Anaxagoras, best known to the world as the teacher of Socrates, we are indebted for the most important service to the atomic theory, which, after its statement by Democritus, remained to be done. Anaxagoras, in fact, stated a theory which so exactly contradicts the atomic theory of Democritus that the truth or falsehood of the one theory implies the falsehood or truth of the other. The question of the existence or non-existence of atoms cannot be presented to us this evening with greater clearness than in the alternative theories of these two philosophers.

Take any portion of matter, say a drop of water, and observe its properties. Like every other portion of matter we have ever seen, it is divisible. Divide it in two, each portion appears to retain all the properties of the original drop, and among others that of being divisible. The parts are similar to the whole in every respect except in absolute size.

Now go on repeating the process of division till the separate portions of water are so small that we can no longer perceive or handle them. Still we have no doubt that the sub-division might be carried further, if our senses were more acute and our instruments more delicate. Thus far all are agreed, but now the question arises, Can this sub-division be repeated for ever?

According to Democritus and the atomic school, we must answer in the negative. After a certain number of sub-divisions, the drop would be divided into a number of parts each of which is incapable of further sub-division. We should thus, in imagination, arrive at the atom, which, as its name literally signifies, cannot be cut in two. This is the atomic doctrine of Democritus, Epicurus, and Lucretius, and, I may add, of your lecturer.

According to Anaxagoras, on the other hand, the parts into which the drop is divided, are in all respects similar to the whole drop, the mere size of a body counting for nothing as regards the nature of its substance. Hence if the whole drop is divisible, so are its parts down to the minutest sub-divisions, and that without end.

The essence of the doctrine of Anaxagoras is that the parts of a body are in all respects similar to the whole. It was therefore called the doctrine of Homoiomereia. Anaxagoras did not of course assert this of the parts of organised bodies such as men and animals, but he maintained that those inorganic substances which appear to us homogeneous are really so, and that the universal experience of mankind testifies that every material body, without exception, is divisible.

The doctrine of atoms and that of homogeneity are thus in direct contradiction.

But we must now go on to molecules. Molecule is a modern word. It does not occur in *Johnson's Dictionary*. The ideas it embodies are those belonging to modern chemistry.

A drop of water, to return to our former example, may be divided into a certain number, and no more, of portions similar to each other. Each of these the modern chemist calls a molecule of water. But it is by no means an atom, for it contains two different substances, oxygen and hydrogen, and by a certain process the molecule may be actually divided into two parts, one consisting of oxygen and the other of hydrogen. According to the received doctrine, in each molecule of water there are two molecules of hydrogen and one of oxygen. Whether these are or are not ultimate atoms I shall not attempt to decide.

We now see what a molecule is, as distinguished from an atom.

A molecule of a substance is a small body such that if, on the one hand, a number of similar molecules were assembled together they would form a mass of that substance, while on the other hand, if any portion of this molecule were removed, it would no longer be able, along with an assemblage of other molecules similarly treated, to make up a mass of the original substance.

Every substance, simple or compound, has its own molecule. If this molecule be divided, its parts are molecules of a different substance or substances from that of which the whole is a molecule. An atom, if there is such a thing, must be a molecule of an elementary substance. Since, therefore, every molecule is not an atom, but every atom is a molecule, I shall use the word molecule as the more general term.

I have no intention of taking up your time by expounding the doctrines of modern chemistry with respect to the molecules of different substances. It is not the special but the universal interest of molecular science which encourages me to address you. It is not because we happen to be chemists or physicists or specialists of any kind that we are attracted towards this centre of all material existence, but because we all belong to a race endowed with faculties which urge us on to search deep and ever deeper into the nature of things.

We find that now, as in the days of the earliest physical speculations, all physical researches appear to converge towards the same point, and every inquirer, as he looks forward into the dim region towards which the path of discovery is leading him, sees, each according to his sight, the vision of the same quest.

One may see the atom as a material point, invested and surrounded by potential forces. Another sees no garment of force, but only the bare and utter hardness of mere impenetrability.

But though many a speculator, as he has seen the vision recede before him into the innermost sanctuary of the inconceivably little, has had to confess that the quest was not for him, and though philosophers in every age have been exhorting each other to direct their minds to some more useful and attainable aim, each generation, from the earliest dawn of science to the present time, has contributed a due proportion of its ablest intellects to the quest of the ultimate atom.

Our business this evening is to describe some researches in molecular science, and in particular to place before you any definite information which has been obtained respecting the molecules themselves. The old atomic theory, as described by Lucretius and revived in modern times, asserts that the molecules of all bodies are in motion, even when the body itself appears to be at rest. These motions of molecules are in the case of solid bodies confined within so narrow a range that even with our best microscopes we cannot detect that they alter their places at all. In liquids and gases, however, the molecules are not confined within any definite limits, but work their way through the whole mass, even when that mass is not disturbed by any visible motion.

This process of diffusion, as it is called, which goes on in gases and liquids and even in some solids, can be subjected to experiment, and forms one of the most convincing proofs of the motion of molecules.

Now the recent progress of molecular science began with the study of the mechanical effect of the impact of these moving molecules when they strike against any solid body. Of course these flying molecules must beat against whatever is placed among them, and the constant succession of these strokes is, according to our theory, the sole cause of what is called the pressure of air and other gases.

This appears to have been first suspected by Daniel Bernoulli, but he had not the means which we now have of verifying the theory. The same theory was afterwards brought forward independently by Lesage, of Geneva, who, however, devoted most of his labour to the explanation of gravitation by the impact of atoms. Then Herapath, in his "Mathematical Physics,"

* Lecture delivered before the British Association at Bradford, by Prof. Clerk-Maxwell, F.R.S.

published in 1847, made a much more extensive application of the theory to gases, and Dr. Joule, whose absence from our meeting we must all regret, calculated the actual velocity of the molecules of hydrogen.

The further development of the theory is generally supposed to have been begun with a paper by Krönig, which does not, however, so far as I can see, contain any improvement on what had gone before. It seems, however, to have drawn the attention of Prof. Clausius to the subject, and to him we owe a very large part of what has been since accomplished.

We all know that air or any other gas placed in a vessel presses against the sides of the vessel, and against the surface of any body placed within it. On the kinetic theory this pressure is entirely due to the molecules striking against these surfaces, and thereby communicating to them a series of impulses which follow each other in such rapid succession that they produce an effect which cannot be distinguished from that of a continuous pressure.

If the velocity of the molecules is given, and the number varied, then since each molecule, on an average, strikes the side of the vessel the same number of times, and with an impulse of the same magnitude, each will contribute an equal share to the whole pressure. The pressure in a vessel of given size is therefore proportional to the number of molecules in it, that is to the quantity of gas in it.

This is the complete dynamical explanation of the fact discovered by Robert Boyle, that the pressure of air is proportional to its density. It shows also that of different portions of gas forced into a vessel, each produces its own part of the pressure independently of the rest, and this whether these portions be of the same gas or not.

Let us next suppose that the velocity of the molecules is increased. Each molecule will now strike the sides of the vessel a greater number of times in a second, but besides this, the impulse of each blow will be increased in the same proportion, so that the part of the pressure due to each molecule will vary as the *square* of the velocity. Now the increase of the square of velocity corresponds, in our theory, to a rise of temperature, and in this way we can explain the effect of warming the gas, and also the law discovered by Charles that the proportional expansion of all gases between given temperatures is the same.

The dynamical theory also tells us what will happen if molecules of different masses are allowed to knock about together. The greater masses will go slower than the smaller ones, so that, on an average, every molecule, great or small, will have the same energy of motion.

The proof of this dynamical theorem, in which I claim the priority, has recently been greatly developed and improved by Dr. Ludwig Boltzmann. The most important consequence which flows from it is that a cubic centimetre of every gas at standard temperature and pressure contains the same number of molecules. This is the dynamical explanation of Gay Lussac's law of the equivalent volumes of gases. But we must now descend to particulars, and calculate the actual velocity of a molecule of hydrogen.

A cubic centimetre of hydrogen, at the temperature of melting ice and at a pressure of one atmosphere, weighs 0·00008954 grammes. We have to find at what rate this small mass must move (whether altogether or in separate molecules makes no difference) so as to produce the observed pressure on the sides of the cubic centimetre. This is the calculation which was first made by Dr. Joule, and the result is 1,859 metres per second. This is what we are accustomed to call a great velocity. It is greater than any velocity obtained in artillery practice. The velocity of other gases is less, as you will see by the table, but in all cases it is very great as compared with that of bullets.

We have now to conceive the molecules of the air in this hall flying about in all directions, at a rate of about seventeen miles in a minute.

If all these molecules were flying in the same direction, they would constitute a wind blowing at the rate of seventeen miles a minute, and the only wind which approaches this velocity is that which proceeds from the mouth of a cannon. How, then, are you and I able to stand here? Only because the molecules happen to be flying in different directions, so that those which strike against our backs enable us to support the storm which is beating against our faces. Indeed, if this molecular bombardment were to cease, even for an instant, our veins would swell, our breath would leave us, and we should, literally, expire. But it is not only against us or against the walls of the room that the molecules are striking. Consider the immense number of them, and the fact that they are flying in every possible direction, and you will see that they cannot avoid striking each other. Every time that two molecules come into collision, the paths of both are changed, and they go off in new directions. Thus each molecule is continually getting its course altered, so that in spite of its great velocity it may be a long time before it reaches any great distance from the point at which it set out.

I have here a bottle containing ammonia. Ammonia is a gas which you can recognise by its smell. Its molecules have a velocity of six hundred metres per second, so that if their course had not been interrupted by striking against the molecules of air in the hall, everyone in the most distant gallery would have smelt ammonia before I was able to pronounce the name of the gas. But instead of this, each molecule of ammonia is so jostled about by the molecules of air, that it is sometimes going one way and sometimes another. It is like a hare which is always doubling, and though it goes a great pace, it makes very little progress. Nevertheless, the smell of ammonia is now beginning to be perceptible at some distance from the bottle. The gas does diffuse itself through the air, though the process is a slow one, and if we could close up every opening of this hall so as to make it air-tight, and leave everything to itself for some weeks, the ammonia would become uniformly mixed through every part of the air in the hall.

This property of gases, that they diffuse through each other, was first remarked by Priestley. Dalton showed that it takes place quite independently of any chemical action between the inter-diffusing gases. Graham, whose researches were especially directed towards those phenomena which seem to throw light on molecular motions, made a careful study of diffusion, and obtained the first results from which the rate of diffusion can be calculated.

Still more recently the rates of diffusion of gases into each other have been measured with great precision by Prof. Loschmidt of Vienna.

He placed the two gases in two similar vertical tubes, the lighter gas being placed above the heavier, so as to avoid the formation of currents. He then opened a sliding valve, so as to make the two tubes into one, and after leaving the gases to themselves for an hour or so, he shut the valve, and determined how much of each gas had diffused into the other.

As most gases are invisible, I shall exhibit gaseous diffusion to you by means of two gases, ammonia and hydrochloric acid, which, when they meet, form a solid product. The ammonia, being the lighter gas, is placed above the hydrochloric acid, with a stratum of air between, but you will soon see that the gases can diffuse through this stratum of air, and produce a cloud of white smoke when they meet. During the whole of this process no currents or any other visible motion can be detected. Every part of the vessel appears as calm as a jar of undisturbed air.

But, according to our theory, the same kind of motion is going on in calm air as in the inter-diffusing gases, the only difference being that we can trace the molecules from one place to another more easily when they are of a different nature from those through which they are diffusing.

If we wish to form a mental representation of what is going on among the molecules in calm air, we cannot do better than observe a swarm of bees, when every individual bee is flying furiously, first in one direction, and then in another, while the swarm, as a whole, either remains at rest, or sails slowly through the air.

In certain seasons, swarms of bees are apt to fly off to a great distance, and the owners, in order to identify their property when they find them on other people's ground, sometimes throw handfulls of flour at the swarm. Now let us suppose that the flour thrown at the flying swarm has whitened those bees only which happened to be in the lower half of the swarm, leaving those in the upper half free from flour.

If the bees still go on flying hither and thither in an irregular manner, the floury bees will be found in continually increasing proportions in the upper part of the swarm, till they have become equally diffused through every part of it. But the reason of this diffusion is not because the bees were marked with flour, but because they are flying about. The only effect of the marking is to enable us to identify certain bees.

We have no means of marking a select number of molecules of air, so as to trace them after they have become diffused among

others, but we may communicate to them some property by which we may obtain evidence of their diffusion.

For instance, if a horizontal stratum of air is moving horizontally, molecules diffusing out of this stratum into those above and below will carry their horizontal motion with them, and so tend to communicate motion to the neighbouring strata, while molecules diffusing out of the neighbouring strata into the moving one will tend to bring it to rest. The action between the strata is somewhat like that of two rough surfaces, one of which slides over the other, rubbing on it. Friction is the name given to this action between solid bodies; in the case of fluids it is called internal friction or viscosity.

It is in fact only another kind of diffusion—a lateral diffusion of momentum, and its amount can be calculated from data derived from observations of the first kind of diffusion, that of matter. The comparative values of the viscosity of different gases were determined by Graham in his researches on the transpiration of gases through long narrow tubes, and their absolute values have been deduced from experiments on the oscillation of discs by Oscar Meyer and myself.

Another way of tracing the diffusion of molecules through calm air is to heat the upper stratum of the air in a vessel, and so observe the rate at which this heat is communicated to the lower strata. This, in fact, is a third kind of diffusion—that of energy, and the rate at which it must take place was calculated from data derived from experiments on viscosity before any direct experiments on the conduction of heat had been made. Prof. Stefan, of Vienna, has recently, by a very delicate method, succeeded in determining the conductivity of air, and he finds it, as he tells us, in striking agreement with the value predicted by the theory.

All these three kinds of diffusion—the diffusion of matter, of momentum, and of energy—are carried on by the motion of the molecules. The greater the velocity of the molecules and the farther they travel before their paths are altered by collision with other molecules, the more rapid will be the diffusion. Now we know already the velocity of the molecules, and therefore by experiments on diffusion we can determine how far, on an average, a molecule travels without striking another. Prof. Clausius, of Bonn, who first gave us precise ideas about the motion of agitation of molecules, calls this distance the mean path of a molecule. I have calculated, from Prof. Loschmidt's diffusion experiments, the mean path of the molecules of four well-known gases. The average distance travelled by a molecule between one collision and another is given in the table. It is a very small distance, quite imperceptible to us even with our best microscopes. Roughly speaking, it is about the tenth part of the length of a wave of light, which you know is a very small quantity. Of course the time spent on so short a path by such swift molecules must be very small. I have calculated the number of collisions which each must undergo in a second. They are given in the table and are reckoned by thousands of millions. No wonder that the travelling power of the swiftest molecule is but small, when its course is completely changed thousands of millions of times in a second.

The three kinds of diffusion also take place in liquids, but the relation between the rates at which they take place is not so simple as in the case of gases. The dynamical theory of liquids is not so well understood as that of gases, but the principal difference between a gas and a liquid seems to be that in a gas each molecule spends the greater part of its time in describing its free path, and is for a very small portion of its time engaged in encounters with other molecules, whereas in a liquid the molecule has hardly any free path, and is always in a state of close encounter with other molecules.

Hence in a liquid the diffusion of motion from one molecule to another takes place much more rapidly than the diffusion of the molecules themselves, for the same reason that it is more expeditious in a dense crowd to pass on a letter from hand to hand than to give it to a special messenger to work his way through the crowd. I have here a jar, the lower part of which contains a solution of copper sulphate, while the upper part contains pure water. It has been standing here since Friday, and you see how little progress the blue liquid has made in diffusing itself through the water above. The rate of diffusion of a solution of sugar has been carefully observed by Voit. Comparing his results with those of Loschmidt on gases, we find that about as much diffusion takes place in a second in gases as requires a day in liquids.

The rate of diffusion of momentum is also slower in liquids than in gases, but by no means in the same proportion. The same amount of motion takes about ten times as long to subside in water as in air, as you will see by what takes place when I stir these two jars, one containing water and the other air. There is still less difference between the rates at which a rise of temperature is propagated through a liquid and through a gas.

In solids the molecules are still in motion, but their motions are confined within very narrow limits. Hence the diffusion of matter does not take place in solid bodies, though that of motion and heat takes place very freely. Nevertheless, certain liquids can diffuse through colloid solids, such as jelly and gum, and hydrogen can make its way through iron and palladium.

We have no time to do more than mention that most wonderful molecular motion which is called electrolysis. Here is an electric current passing through acidulated water, and causing oxygen to appear at one electrode and hydrogen at the other. In the space between, the water is perfectly calm, and yet two opposite currents of oxygen and of hydrogen must be passing through it. The physical theory of this process has been studied by Clausius, who has given reasons for asserting that in ordinary water the molecules are not only moving, but every now and then striking each other with such violence that the oxygen and hydrogen of the molecules part company, and dance about through the crowd, seeking partners which have become dissociated in the same way. In ordinary water these exchanges produce, on the whole, no observable effect, but no sooner does the electromotive force begin to act than it exerts its guiding influence on the unattached molecules, and bends the course of each toward its proper electrode, till the moment when, meeting with an unappropriated molecule of the opposite kind, it enters again into a more or less permanent union with it till it is again dissociated by another shock. Electrolysis, therefore, is a kind of diffusion assisted by electromotive force.

Another branch of molecular science is that which relates to the exchange of molecules between a liquid and a gas. It includes the theory of evaporation and condensation, in which the gas in question is the vapour of the liquid, and also the theory of the absorption of a gas by a liquid of a different substance. The researches of Dr. Andrews on the relations between the liquid and the gaseous state have shown us that though the statements in our own elementary text-books may be so neatly expressed that they appear almost self-evident, their true interpretation may involve some principle so profound that, till the right man has laid hold of it, no one ever suspects that anything is left to be discovered.

These, then, are, some of the fields from which the data of molecular science are gathered. We may divide the ultimate results into three ranks, according to the completeness of our knowledge of them.

To the first rank belong the relative masses of the molecules of different gases, and their velocities in metres per second. These data are obtained from experiments on the pressure and density of gases, and are known to a high degree of precision.

In the second rank we must place the relative size of the molecules of different gases, the length of their mean paths, and the number of collisions in a second. These quantities are deduced from experiments on the three kinds of diffusion. Their received values must be regarded as rough approximations till the methods of experimenting are greatly improved.

There is another set of quantities which we must place in the third rank, because our knowledge of them is neither precise, as in the first rank, nor approximate, as in the second, but is only as yet of the nature of a probable conjecture. These are the absolute mass of a molecule, its absolute diameter, and the number of molecules in a cubic centimetre. We know the relative masses of different molecules with great accuracy, and we know their relative diameters approximately. From these we can deduce the relative densities of the molecules themselves. So far we are on firm ground.

The great resistance of liquids to compression makes it probable that their molecules must be at about the same distance from each other as that at which two molecules of the same substance in the gaseous form act on each other during an encounter. This conjecture has been put to the test by Lorenz Meyer, who has compared the densities of different liquids with the calculated relative densities of the molecules of their vapours, and has found a remarkable correspondence between them.

Now Loschmidt has deduced from the dynamical theory the

following remarkable proportion:—As the volume of a gas is to the combined volume of all the molecules contained in it, so is the mean path of a molecule to one-eighth of the diameter of a molecule.

Assuming that the volume of the substance, when reduced to the liquid form, is not much greater than the combined volume of the molecules, we obtain from this proportion the diameter of a molecule. In this way Loschmidt, in 1865, made the first estimate of the diameter of a molecule. Independently of him and of each other, Mr. Stoney in 1868, and Sir W. Thomson in 1870, published results of a similar kind, those of Thomson being deduced not only in this way, but from considerations derived from the thickness of soap bubbles, and from the electric properties of metals.

According to the table, which I have calculated from Loschmidt's data, the size of the molecules of hydrogen is such that about two million of them in a row would occupy a millimetre, and a million million million million of them would weigh between four and five grammes.

In a cubic centimetre of any gas at standard pressure and temperature there are about nineteen million million million molecules. All these numbers of the third rank are, I need not tell you, to be regarded as at present conjectural. In order to warrant us in putting any confidence in numbers obtained in this way, we should have to compare together a greater number of independent data than we have as yet obtained, and to show that they lead to consistent results.

Thus far we have been considering molecular science as an inquiry into natural phenomena. But though the professed aim of all scientific work is to unravel the secrets of nature, it has another effect, not less valuable, on the mind of the worker. It leaves him in possession of methods which nothing but scientific work could have led him to invent, and it places him in a position from which many regions of nature, besides that which he has been studying, appear under a new aspect.

The study of molecules has developed a method of its own, and it has also opened up new views of nature.

When Lucretius wishes us to form a mental representation of the motion of atoms, he tells us to look at a sunbeam shining through a darkened room (the same instrument of research by which Dr. Tyndall makes visible to us the dust we breathe,) and to observe the motes which chase each other in all directions through it. This motion of the visible motes, he tells us, is but a result of the far more complicated motion of the invisible atoms which knock the motes about. In his dream of nature, as Tennyson tells us, he

> "saw the flaring atom-streams
> And torrents of her myriad universe,
> Ruining along the illimitable inane,
> Fly on to clash together again, and make
> Another and another frame of things
> For ever."

And it is no wonder that he should have attempted to burst the bonds of Fate by making his atoms deviate from their courses at quite uncertain times and places, thus attributing to them a kind of irrational free will, which on his materialistic theory is the only explanation of that power of voluntary action of which we ourselves are conscious.

As long as we have to deal with only two molecules, and have all the data given us, we can calculate the result of their encounter, but when we have to deal with millions of molecules, each of which has millions of encounters in a second, the complexity of the problem seems to shut out all hope of a legitimate solution.

The modern atomists have therefore adopted a method which is I believe new in the department of mathematical physics, though it has long been in use in the Section of Statistics. When the working members of Section F get hold of a Report of the Census, or any other document containing the numerical data of Economic and Social Science, they begin by distributing the whole population into groups, according to age, income-tax, education, religious belief, or criminal convictions. The number of individuals is far too great to allow of their tracing the history of each separately, so that, in order to reduce their labour within human limits, they concentrate their attention on a small number of artificial groups. The varying number of individuals in each group, and not the varying state of each individual, is the primary datum from which they work.

This, of course, is not the only method of studying human nature. We may observe the conduct of individual men and compare it with that conduct which their previous character and their present circumstances, according to the best existing theory, would lead us to expect. Those who practise this method endeavour to improve their knowledge of the elements of human nature, in much the same way as an astronomer corrects the elements of a planet by comparing its actual position with that deduced from the received elements. The study of human nature by parents and schoolmasters, by historians and statesmen, is therefore to be distinguished from that carried on by registrars and tabulators, and by those statesmen who put their faith in figures. The one may be called the historical, and the other the statistical method.

The equations of dynamics completely express the laws of the historical method as applied to matter, but the application of these equations implies a perfect knowledge of all the data. But the smallest portion of matter which we can subject to experiment consists of millions of molecules, not one of which ever becomes individually sensible to us. We cannot, therefore, ascertain the actual motion of any one of these molecules, so that we are obliged to abandon the strict historical method, and to adopt the statistical method of dealing with large groups of molecules.

The data of the statistical method as applied to molecular science are the sums of large numbers of molecular quantities. In studying the relations between quantities of this kind, we meet with a new kind of regularity, the regularity of averages, which we can depend upon quite sufficiently for all practical purposes, but which can make no claim to that character of absolute precision which belongs to the laws of abstract dynamics.

Thus molecular science teaches us that our experiments can never give us anything more than statistical information, and that no law deduced from them can pretend to absolute precision. But when we pass from the contemplation of our experiments to that of the molecules themselves, we leave the world of chance and change, and enter a region where everything is certain and immutable.

The molecules are conformed to a constant type with a precision which is not to be found in the sensible properties of the bodies which they constitute. In the first place the mass of each individual molecule, and all its other properties, are absolutely unalterable. In the second place the properties of all molecules of the same kind are absolutely identical.

Let us consider the properties of two kinds of molecules, those of oxygen and those of hydrogen.

We can procure specimens of oxygen from very different sources—from the air, from water, from rocks of every geological epoch. The history of these specimens has been very different, and if, during thousands of years, difference of circumstances could produce difference of properties, these specimens of oxygen would show it.

In like manner we may procure hydrogen from water, from coal, or, as Graham did, from meteoric iron. Take two litres of any specimen of hydrogen, it will combine with exactly one litre of any specimen of oxygen, and will form exactly two litres of the vapour of water.

Now if, during the whole previous history of either specimen, whether imprisoned in the rocks, flowing in the sea, or careering through unknown regions with the meteorites, any modification of the molecules had taken place, these relations would no longer be preserved.

But we have another and an entirely different method of comparing the properties of molecules. The molecule, though indestructible, is not a hard rigid body, but is capable of internal movements, and when these are excited it emits rays, the wave-length of which is a measure of the time of vibration of the molecule.

By means of the spectroscope the wave-lengths of different kinds of light may be compared to within one ten-thousandth part. In this way it has been ascertained, not only that molecules taken from every specimen of hydrogen in our laboratories have the same set of periods of vibration, but that light, having the same set of periods of vibration, is emitted from the sun and from the fixed stars.

We are thus assured that molecules of the same nature as those of our hydrogen exist in those distant regions, or at least did exist when the light by which we see them was emitted.

From a comparison of the dimensions of the buildings of the Egyptians with those of the Greeks, it appears that they have a common measure. Hence, even if no ancient author had recorded the fact that the two nations employed the same cubit as a standard of length, we might prove it from the buildings themselves. We should also be justified in asserting that at some time or other a material standard of length must have been

carried from one country to the other, or that both countries had obtained their standards from a common source.

But in the heavens we discover by their light, and by their light alone, stars so distant from each other that no material thing can ever have passed from one to another, and yet this light, which is to us the sole evidence of the existence of these distant worlds, tells us also that each of them is built up of molecules of the same kinds as those which we find on earth. A molecule of hydrogen, for example, whether in Sirius or in Arcturus, executes its vibrations in precisely the same time.

Each molecule, therefore, throughout the universe, bears impressed on it the stamp of a metric system as distinctly as does the metre of the Archives at Paris, or the double royal cubit of the Temple of Karnac.

No theory of evolution can be formed to account for the similarity of molecules, for evolution necessarily implies continuous change, and the molecule is incapable of growth or decay, of generation or destruction.

None of the processes of Nature, since the time when Nature began, have produced the slightest difference in the properties of any molecule. We are therefore unable to ascribe either the existence of the molecules or the identity of their properties to the operation of any of the causes which we call natural.

On the other hand, the exact quality of each molecule to all others of the same kind gives it, as Sir John Herschel has well said, the essential character of a manufactured article, and precludes the idea of its being eternal and self existent.

Thus we have been led, along a strictly scientific path, very near to the point at which Science must stop. Not that Science is debarred from studying the internal mechanism of a molecule which she cannot take to pieces, any more than from investigating an organism which she cannot put together. But in tracing back the history of matter Science is arrested when she assures herself, on the one hand, that the molecule has been made, and on the other that it has not been made by any of the processes we call natural.

Science is incompetent to reason upon the creation of matter itself out of nothing. We have reached the utmost limit of our thinking faculties when we have admitted that because matter cannot be eternal and self-existent it must have been created.

It is only when we contemplate, not matter in itself, but the form in which it actually exists, that our mind finds something on which it can lay hold.

That matter, as such, should have certain fundamental properties—that it should exist in space and be capable of motion, that its motion should be persistent, and so on, are truths which may, for anything we know, be of the kind which metaphysicians call necessary. We may use our knowledge of such truths for purposes of deduction but we have no data for speculating as to their origin.

But that there should be exactly so much matter and no more in every molecule of hydrogen is a fact of a very different order. We have here a particular distribution of matter—a *collocation*—to use the expression of Dr. Chalmers, of things which we have no difficulty in imagining to have been arranged otherwise.

The form and dimensions of the orbits of the planets, for instance, are not determined by any law of nature, but depend upon a particular collocation of matter. The same is the case with respect to the size of the earth, from which the standard of what is called the metrical system has been derived. But these astronomical and terrestrial magnitudes are far inferior in scientific importance to that most fundamental of all standards which forms the base of the molecular system. Natural causes, as we know, are at work, which tend to modify, if they do not at length destroy, all the arrangements and dimensions of the earth and the whole solar system. But though in the course of ages catastrophes have occurred and may yet occur in the heavens, though ancient systems may be dissolved and new systems evolved out of their ruins, the molecules out of which these systems are built—the foundation stones of the material universe—remain unbroken and unworn.

They continue this day as they were created, perfect in number and measure and weight, and from the ineffaceable characters impressed on them we may learn that those aspirations after accuracy in measurement, truth in statement, and justice in action, which we reckon among our noblest attributes as men, are ours because they are essential constituents of the image of Him Who in the beginning created, not only the heaven and the earth, but the materials of which heaven and earth consist.

Table of Molecular Data.

		Hydrogen.	Oxygen.	Carbonic oxide.	Carbonic acid.
Rank I.	Mass of molecule (hydrogen = 1)	1	16	14	22

FUEL *

IN accepting the invitation of the Council of the British Association to deliver an address to the operative classes of this great industrial district, I felt that I was undertaking no easy task. Having to speak on behalf of the Association, and in the presence of many of its most distinguished members, I am bound to treat my subject scientifically, but I have to bear in mind at the same time that I am addressing myself to men unquestionably of good intelligence, but without that scientific training which has almost created a language of its own.

It is no consolation for me to think, that those who have taken a similar task upon themselves in former years, have admirably succeeded in divesting highly scientific subjects of the formalism in which they are habitually clothed. The very names of these men—Tyndall, Huxley, Miller, Lubbock, and Spottiswoode—are such as to preclude in me all idea of rivalry, but I hope to profit by their example, and to remember that truth must always be simple, and that it is only where knowledge is imperfect that scientific formulæ must take the place of plain statements.

The subject matter of my discourse is "Fuel;" a matter with which every one of us has become familiarised from his infancy, but which nevertheless is but little understood even by those who are most largely interested in its applications; it involves considerations of the highest *à priori* interest, both from a scientific and a practical point of view.

I purpose to arrange my subject under five principal heads:—

1. What is fuel?
2. Whence is fuel derived?
3. How should fuel be used?
4. The coal question of the day.
5. Wherein consists the fuel of the sun?

What is fuel?—Some of you may have already said within yourselves that it is but wasted time to enlarge upon such a

* Lecture delivered before the British Association at Bradford, by Dr. Siemens.

theme, since all know that fuel is coal drawn from the earth from deposits, with which this country especially has been bountifully supplied; why disturb our plain understanding by scientific definitions which will neither reduce the cost of coal, nor make it last longer on our domestic hearth?

Yet I must claim your patience for a little, lest, if we do not first agree upon the essential nature of fuel, we may afterwards be at variance in discussing its origin and its uses, the latter at any rate being of practical interest, and a subject worthy of your most attentive consideration.

Fuel, then, in the ordinary acceptation of the term, is carbonaceous matter, which may be in the solid, the liquid, or in the gaseous condition, and which, in combining with oxygen, gives rise to the phenomenon of heat. Commonly speaking, this development of heat is accompanied by flame, because the substance produced in combustion is gaseous. In burning coal, for instance, on a fire-grate, the oxygen of the atmosphere enters into combination with the solid carbon of the coal and produces carbonic acid—a gas which enters the atmosphere, of which it forms a necessary constituent, since without it the growth of trees and other plants would be impossible. But combustion is not necessarily accompanied by flame, or even by a display of intense heat. The metal magnesium burns with a great display of light and heat, but without flame, because the product of combustion is not a gas but a solid, viz. oxide of magnesia. Again, metallic iron, if in a finely divided state, ignites when exposed to the atmosphere, giving rise to the phenomena of heat and light without flame, because the result of combustion is iron oxide or rust; but the same iron, if presented to the atmosphere—more especially to a damp atmosphere—in a solid condition, does not ignite, but is nevertheless gradually converted into metallic oxide or rust as before.

Here, then, we have combination without the phenomena either of flame or light; but by careful experiment we should find that heat is nevertheless produced, and that the amount of heat so produced precisely equals that obtained more rapidly in exposing spongy iron to the action of oxygen. Only, in the latter case the heat is developed by slow degrees, and is dispersed as soon as produced; whereas in the former the rate of production exceeds the rate of dispersion, and heat, therefore, accumulates to the extent of raising the mass to redness. It is evident from these experiments that we have to widen our conception, and call fuel "any substance which is capable of entering into combination with another substance, and in so doing gives rise to the phenomenon of heat."

In thus defining fuel, it might appear at first sight that we should find upon our earth a great variety, and an inexhaustible supply of substances that might be ranged under this head; but a closer investigation will soon reveal the fact that its supply is, comparatively speaking, extremely limited.

In looking at the solid crust of the earth, we find it to be composed for the most part of siliceous, calcareous, and magnesian rock; the former, silica, consisting of the metal silicon combined with oxygen, and is therefore not fuel, but rather a burnt substance which has parted with its heat of combustion ages ago; the second limestone, being carbonate of lime, or the combination of two substances, viz., oxide of calcium and carbonic acid, both of which are essentially products of combustion, the one of the metal calcium and the other of carbon; and the third, magnesia, being the substance magnesium, which I have just burnt before you, and which, further combined with lime, constitutes dolomite rock, of which the Alps are mainly composed. All the commoner metals, such as iron, zinc, tin, alumina, sodium, &c., we find in nature in an oxidised or burnt condition; and the only metallic substances that have resisted the intense oxidising action that must have prevailed at one period of the earth's creation are the so-called precious metals, gold, platinum, iridium, and to some extent also silver and copper. But what about the oceans of water, which have occasionally been cited as representing a vast store of heat-producing power ready for our use when coal shall be exhausted? Not many months ago, indeed, on the occasion of a water-gas company being formed, statements to this effect could be seen in some of our leading papers. Nothing, however, could be more fallacious. When hydrogen burns, doubtless a great development of heat ensues, but water is already the result of this combustion (which took place upon the globe before the ocean was formed), and the separation of these two substances would take precisely the same amount of heat as was originally produced in the combustion. It will thus be seen that both the solid and fluid constituents of our earth, with the exception of coal, of naphtha (which is a mere modification of coal), and the precious metals, are products of combustion, and therefore the very reverse of fuel. Our earth may indeed be looked upon as "a ball of cinder, rolling eternally through space," but happily in company with another celestial body—the sun—whose glorious beams are the physical cause of everything that moves and lives, or that has the power within itself of imparting life, heat, or motion. The invigorating influence is made perceptible to our senses in the form of heat, but it is fair to ask, what is heat, that it should be capable of coming to us from the sun, and of being treasured up in our fuel deposits both below and on the surface of the earth?

If this inquiry had been put to me thirty years ago, I should have been much perplexed. By reference to books on Physical Science, I should have learnt that heat was a subtle fluid which, somehow or other, had taken up its residence in the fuel, and which, upon ignition of the latter, was sallying forth either to vanish or to abide elsewhere; but I should not have been able to associate the two ideas of combustion and development of heat by any intelligible principle in nature, or to suggest any process by which it could have been derived from the sun and petrified, or, as the empty phrase ran, rendered latent in the fuel.

It is by the labours of Meyer, Joule, Clausius, Ranken, and other modern physicists, that we are enabled to give to heat its true significance.

Heat, according to the "dynamical theory," is neither more nor less than motion amongst the particles of the substance heated, which motion, when once produced, may be changed in its direction and its nature, and thus be converted into mechanical effect, expressible in foot pounds, or horse power. By intensifying this motion among the particles, it is made evident to our visual organ by the emanation of light, which again is neither more nor less than vibratory motion imparted by the ignited substance to the medium separating us from the same. According to this theory, which constitutes one of the most important advances in science of the present century, heat, light, electricity, and chemical action are only different manifestations of "energy of matter," mutually convertible, but as indestructible as matter itself.

Energy exists in two forms, dynamic or "kinetic energy," or force manifesting itself to our senses as weight in motion, as sensible heat, or as an active electrical current; and "potential energy," or force in a dormant condition. In illustration of these two forms of energy, I will take the case of lifting a weight, say one pound one foot high. In lifting this weight "kinetic muscular energy" has to be exercised in overcoming the force of gravitation of the earth. The pound weight when supported at the higher level to which it has been raised, represents potential energy to the amount of one unit or foot pound. This potential energy may be utilised in imparting motion to mechanism during its descent, whereby a unit amount of "Work" is accomplished. A pound of carbon then, when raised through the space of one foot from the earth, represents, mechanically speaking, a unit quantity of energy, but the same pound of carbon being separated or lifted away from oxygen, to which it has a very powerful attraction, is capable of developing no less than 11,000,000 foot pounds or unit quantities of energy whenever the bar to their combination, namely excessive depression of temperature, is removed; in other words, the mechanical energy set free in the combustion of one pound of pure carbon is the same as would be required to raise 11,000,000 pounds weight one foot high, or as would sustain the work which we call a horse power during 5 hours 33 minutes. We thus arrive at once at the utmost limit of work which we can ever hope to accomplish by the combustion of one pound of carbonaceous matter, and we shall presently see how far we are still removed in our steam engine practice from this limit of perfection.*

The following illustrations will show the convertibility of the different forms of energy. If I let the weight of a hammer descend in rapid succession upon a piece of iron it becomes hot, and on beating a nail thus vigorously and skilfully for a minute it will be redhot. In this case the mechanical force developed in the arm by the combustion of carbonaceous muscular fibre is converted into heat. Again, in compressing the air in a fire syringe rapidly ignition of a piece of tinder is obtained. Again, in passing an electrical current through the platinum wire it is

* In burning 1 lb. of carbon in the presence of free oxygen, carbonic acid is produced and 14,500 units of heat (1 lb. of water raised through 1° Fah.) are liberated. Each unit of heat is convertible (as proved by the deductions of Meyer and the actual measurements of Joule) into 774 units of force or mechanical energy; hence 1 lb. of carbon represents really 14,500 × 774 = 11,223,000 units of potential energy

directly converted into heat, which is manifested by ignition of the wire, whereas the thermopile gives an illustration of the conversion of heat into electricity. The heat of combustion is the result of the chemical combination of two substances; but does it not follow from this that oxygen is a combustible as well as the carbonaceous substance which goes by the name of fuel? This is, unquestionably, the case, and if our atmosphere was composed of a carbonaceous gas we should have to conduct our oxygen through tubes and send it out through burners to supply us with light and heat, as will be seen by the experiment in which I burn a jet of atmospheric air in a transparent globe filled with common lighting gas; but we could not exist under such inverted conditions, and may safely strike out oxygen and analogous substances such as chlorine from the list of fuels.

We now approach the second part of our inquiry—Whence is fuel derived?

The rays of the sun represent energy in the form of heat and light, which is communicated to our earth through the transparent medium which must necessarily fill the space between us and our great luminary. If these rays fall upon the growing plant, their effect disappears from direct recognition by our senses, inasmuch as the leaf does not become heated as it would if it was made of iron or dead wood, but we find a chemical result accomplished, viz., carbonic acid gas which has been absorbed by the leaf of the tree from the atmosphere, is there "dissociated," or separated into its elements carbon and oxygen, the oxygen being returned to the atmosphere, and the carbon retained to form the solid substance of the tree.

It is thus clearly shown that the sun has to impart 11,000,000 units of energy to the tree for the formation of one pound of carbon in the shape of woody fibre, and that these 11,000,000 units of energy will be simply resuscitated when the wood is burnt, or again combined with oxygen to form carbonic acid.

Fuel, then, is derived through solar energy acting on the surface of our earth.

But what about the stores of mineral fuel, of coal, which we find within its folds? How did they escape the general combustion which, as we have seen, has consumed all other elementary substances? The answer is a simple one. These deposits of mineral fuel are the results of primeval forests, formed in the manner of to-day through the agency of solar rays, and covered over with earthy matter in the many inundations and convulsions of the globe's surface, which must have followed the early solidification of its surface. Thus our deposits of coal may be looked upon as the accumulation of potential energy derived directly from the sun in former ages, or as George Stephenson, with a sagacity of mind in advance of the science of his day, answered, when asked what was the ultimate cause of motion of his locomotive engine, "that it went by the bottled-up rays of the sun."

It follows from these considerations that the amount of potential energy available for our use is confined to our deposits of coal, which, as appears from the exhaustive inquiries lately made by the Royal Coal Commission are still large indeed, but by no means inexhaustible, if we bear in mind that our requirement will be ever on the increase and that the getting of the coal will become from year to year more difficult as we descend to greater depth. To these stores must be reckoned lignite and peat, which, although not coal, are nevertheless the result of solar energy, attributable to a period of the earth's creation subsequent to the formation of the coal beds, but anterior to our own days.

In discussing the necessity of using our stores of fuel more economically, I have been met by the observation that we need not be anxious about leaving fuel for our descendants—that the human mind would surely invent some other source of power when coal should be exhausted, and that such a source would probably be discovered in electricity. I heard such a suggestion publicly made only a few weeks back at a meeting of the International Jury at Vienna, and could not refrain from calling attention to the fact that electricity is only another form of energy, that could no more be created by man than heat could, and involved the same recourse to our accumulated stores.

If our stores of coal were to ebb, we should have recourse, no doubt, to the force radiating from the sun from day to day; and it may be as well for us to consider, what is the extent of that force, and what our means of gathering and applying it. We have, then, in the first place, the accumulation of solar energy upon our earth's surface by the decomposition of carbonic acid in plants, a source which we know by experience suffices for the human requirements in thinly-populated countries, where industry has taken only a slight development. Wherever population accumulates, however, the wood of the forest no longer suffices even for domestic requirements, and mineral fuel has to be transported from great distances.

The sun's rays produce, however, other effects besides vegetation, and amongst these, evaporation is the most important as a source of available power. By the solar rays, an amount of heat is imparted to our earth that would evaporate yearly a lake of water fourteen feet deep. A considerable proportion of this heat is actually expended in evaporating sea water, producing steam or vapour, which falls back upon the entire surface of both land and sea in the form of rain. The portion which falls upon the elevated land flows back towards the sea in the form of rivers, and in its descent its weight may be utilised to give motion to machinery. Water power, therefore, is also the result of solar energy, and an elevated lake may indeed be looked upon as fuel, in the sense of its being a weight lifted above the sea level through its prior expansion into steam.

This source of power has also been largely resorted to, and might be utilised to a still greater extent in mountainous countries; but it naturally so happens that the great centres of industry are in the plains, where the means of transport are easy, and the total amount of available water-power in such districts is extremely limited.

Another result of solar energy are the winds, which have been utilised for the production of power. This source of power is, indeed, very great in the aggregate, but its application is attended with very great inconvenience. It is proverbial that there is nothing more uncertain than the wind, and when we were dependent upon windmills for the production of flour, it often happened that whole districts were without that necessary element to our daily existence. Ships also, relying upon the wind for their propulsion through the sea, are often becalmed for weeks, and so gradually give preference to steam-power on account of its greater certainty. It has been suggested of late years to utilise the heat of the sun by the accumulation of its rays into a focus by means of gigantic lenses, and to establish steam-boilers in such foci. This would be a most direct utilisation of solar energy, but it is a plan which would hardly recommend itself in this country, where the sun is but rarely seen, and which even in a country like Spain would hardly be productive of useful, practical results.

There is one more natural source of energy available for our uses, which is rather cosmical than solar, viz., the tidal wave. This might also be utilised to very considerable extent in an island country facing the Atlantic seas, like this, but its utilisation on a large scale is connected with great practical difficulty and expenditure, on account of the enormous area of tidal basin that would have to be constructed.

In passing in review these various sources of energy which are still available to us, after we have run through our accumulated capital of potential energy in the shape of coal, it will have struck you that none of them would at all supply the place of our willing and ever-ready slave, the steam-engine; nor would they be applicable to our purposes of locomotion, although means might possibly be invented of storing and carrying potential energy in other forms. But it is not force alone that we require, but heat for smelting our iron and other metals, and the accomplishment of other chemical purposes. We also need a large supply for our domestic purposes. It is true that with an abundant supply of mechanical force we could manufacture heat, and thus actually accomplish all our purposes of smelting, cooking, and heating, without the use of any combustible matter; but such conversion would be attended with so much difficulty and expenditure, that one cannot conceive human prosperity under such laborious and artificial conditions.

We come now to the question—How should fuel be used, and I propose to illustrate this by three examples which are typical of the three great branches of consumption.

a. The production of steam power.

b. The domestic hearth.

c. The metallurgical furnace.

I have represented on a diagram two steam cylinders of the same internal dimensions, the one being what is called a high-pressure steam cylinder, provided with the ordinary slide-valve for the admission and discharge of steam into the atmosphere, and the other so arranged as to work expansively (being provided with the Carless variable expansion gear) and working in connection with a condenser. I have also shown two diagrams of

the steam pressures at each part of the stroke, assuming in both cases the same initial steam pressure of 60 lbs. per square inch above the atmospheric pressure, and the same load upon the engine. They show that in the latter case the same amount of work is accomplished by filling the cylinder roughly speaking up to one-third part of the length as in the other by filling it entirely. Here we have then an easy and feasible plan of saving two-thirds of the fuel used in working an ordinary high-pressure engine, and yet probably the greater number of the engines now actually at work are of the wasteful type. Nor are the indications of theory in this case (or in any other when properly interpreted) disproved by practice; on the contrary, an ordinary non-expansive non-condensing engine requires commonly a consumption of from 10 to 12 lbs. per horse-power per hour, whereas a good expansive and condensing engine accomplishes the same amount of work with 2 lbs. of coal per hour, the reason for the still greater economy being, that the cylinder of the good engine is properly protected by means of a steam-jacket and lagging against loss by condensation within the working cylinder, and that more care is generally bestowed upon the boiler and the parts of the engine, to ensure their proper working condition.

A striking illustration of what can be accomplished by way of accuracy in a short space of time was brought to light by the Institute of Mechanical Engineers, over which at present I have the honour to preside. In holding their annual general meeting in Liverpool in 1863, they instituted a careful inquiry into the consumption by the best engines in the Atlantic Steam Service, and the result showed that it fell in no case below $4\frac{1}{2}$ lbs. per indicated horse power per hour. Last year they again assembled with the same object in view in Liverpool, and Mr. Bramwell produced a table showing that the average consumption by 17 good examples of compound expansive engines did not exceed $2\frac{1}{4}$ lbs. per indicated horse power per hour. Mr. E. A. Cowper has proved a consumption not exceeding $1\frac{1}{2}$ lbs. per indicated horse power per hour in a compound marine engine constructed with an intermediate superheating vessel, in accordance with his plans, nor are we likely to stop long at this point of comparative perfection, for in the early portion of my address I have endeavoured to prove that the theoretical perfection would only be attained if an indicated horse power was produced with $\frac{1}{5 \cdot 5}$ lbs. of pure carbon, or say $\frac{1}{4}$ lb. of ordinary steam coal.

Here then we have two distinct margins to work upon, the one up to the limit of say 2 lbs. per horse power per hour, which has been practically reached in some and may be reached in all cases, and the other up to the theoretical limit of $\frac{1}{4}$ lb. per horse power per hour which can never be absolutely reached, but which inventive power may and will enable us to approach!

Domestic Consumption—The wastefulness of the domestic hearth and kitchen fire is self-evident. Here only the heat radiated from the fire itself is utilised, and the combustion is generally extremely imperfect, because the iron back and excessive supply of cold airs, check combustion before it is half completed. We know that we can heat a room much more economically by means of a German stove, but to this it may be very properly objected that it is cheerless, because we do not see the fire or feel its drying effect on our damp clothing; it does not provide, moreover, in a sufficient degree for ventilation, and makes the room feel stuffy. These are, in my opinion, very potent objections, and economy would not be worth having if it could only be obtained at the expense of health and comfort. But there is at least one grate that combines an increased amount of comfort with reasonable economy, and which, although accessible to all, is as yet very little used. I refer to Captain Galton's "Ventilating Fireplace," of which you observe a diagram upon the wall. This fireplace does not differ in external appearance from an ordinary grate, except that it has a higher brick back, which is perforated at about mid-height to admit warmed air into the fire to burn a large proportion of the smoke which is usually sent up the chimney unburnt, for no better purpose than to poison the atmosphere we have to breathe.

The chief novelty and merit of Captain Galton's fireplace consists, however, in providing a chamber at the back of the grate, into which air passes directly from without, becomes moderately heated (to 84° Fah.), and, rising in a separate flue, is injected into the room under the ceiling with a force due to the heated ascending flue. A plenum of pressure is thus established within the room whereby indraughts through doors and windows are avoided, and the air is continually renewed by passing away through the fireplace chimney as usual. Thus the cheerfulness of an open fire, the comfort of a room filled with fresh but moderately warmed air, and great economy of fuel, are happily combined with unquestionable efficiency and simplicity; and yet the grate is little used, although it has been fully described in papers communicated by Captain Galton, and in an elaborate report made by General Morin, le Directeur du Conservatoire des Arts et Metiers of Paris, which has also appeared in the English language.

The slowness with which this unquestionable improvement finds practical application is due, in my opinion, to two circumstances,—the one is, that Captain Galton did not patent his improvement, which makes it nobody's business to force it into use, and the other may be found in the circumstance that houses are, to a great extent, built only to be sold and not to be lived in. A builder thinks it a good speculation to construct a score of houses after a cheap design, in order to sell them, if possible, before completion, and the purchaser immediately puts up the standard bill of "Desirable Residences to Let." You naturally would think that in taking such a house you had only to furnish it to your own mind, and be in the enjoyment of all reasonable creature comfort from the moment you enter the same. This fond hope is destined, however, to cruel disappointment; the first evening you turn on the gas, you find that although the pipes are there, the gas prefers to pass out by the joints into the room instead of by the burners; the water in like manner takes its road through the ceiling, bringing down with it a patch of plaster on to your carpet. But worst of all, the fire-grates (of a size irrespective, probably, of the size of the room), absolutely refuse to avail themselves of the chimney flues preferring to send the volumes of smoke into the room. Plumbers and chimney doctors are now put into requisition, pulling up floors, dirtying carpets, and putting up gaunt-looking chimney-pots; the grates themselves have to be altered again and again, until by slow degrees the house becomes habitable in a degree, although you now only become fully aware of innumerable drawbacks of the arrangements adopted. Nevertheless, the house has been an excellent one to sell, and the builder adopts the same pattern for another block or two in an increasing neighbourhood. Why should this builder adopt Captain Galton's fireplace? It will not cost him much, it is true, and it will save the tenant a great deal in his annual coal bill, not to speak of the comfort it would give him and his family; but nobody demands it of him, it would give him some trouble to arrange his details and subcontracts, which are all settled beforehand, and so he goes on building and selling houses in the usual routine way. Nor will this state of things be altered until the dwellers in houses will take the matter in hand, and absolutely refuse to put up with builders' ways, or, what is still better, get builders who will put up houses in their way. This is done to some extent by building societies, but there is as yet too much of the old leaven left in the trade, and the question itself too little understood.

Consumption in Smelting Operations.—We now come to the third branch of consumption, the smelting or metallurgical furnace, which consumes about 40,000,000 of the 120 millions of the fuel produced. Here also is great room for improvement, the actual fuel consumed in heating a ton of iron up to the welding point or of melting a ton of steel is more in excess of the theoretical quantity required for these purposes than is the case with regard to the production of steam power and to domestic consumption. Taking the specific heat of iron at ·114 and the welding heat at 2,700° F. it would require $2,700 \times \cdot 144$—307 heat units to heat 1 lb. of iron. A pound of pure carbon developes 14,500 heat units, a pound of common coal 12,000, and therefore one ton of coal should bring 39 tons of iron up to the welding point. In an ordinary re-heating furnace a ton of coal heats only $1\frac{3}{5}$ ton of iron, and therefore produces only $\frac{1}{13}$rd part of the maximum theoretical effect. In melting one ton of steel in pots $2\frac{1}{2}$ tons of coke are consumed, and taking the melting point of steel at 3,600° F. the specific heat at ·119 it takes $\cdot 119 \times 3,600 = 428$ heat units to melt a pound of steel, and taking the heat producing power of common coke also at 12,000 units, one ton of coke ought to be able to melt 28 tons of steel. The Sheffield pot steel melting furnace therefore only utilises $\frac{1}{70}$th part of the theoretical heat developed in the combustion. Here therefore is a very wide margin for improvement, to which I have specially devoted my attention for many years, and not without the attainment of useful results. I have since the year

1846, or very shortly after the first announcement of the dynamical theory, devoted my attention to a realisation of some of the economic results which that theory rendered feasible. I fixed upon the regenerator as the appliance which, without being capable of reproducing heat when once really consumed, is extremely useful for temporarily storing such heat as cannot be immediately utilised in order to impart it to the fluid or other substance which is employed in continuation of the operation of heating or of generating force.

Without troubling you with an account of the gradual progress of these improvements, I will describe to you shortly the furnace which I now employ for melting steel. This consists of a furnace bed made of very refractory material, such as pure silica sand and silica or Dina's brick, under which four regenerators or chambers filled with checkerwork of brick are arranged in such a manner that a current of combustible gas passes upward through one of these regenerators, while a current of air passes upwards through the adjoining regenerator, in order to meet in combustion at the entrance into the furnace chamber. The products of combustion, instead of passing directly to the chimney as in an ordinary furnace, are directed downwards through the two other regenerators on their way towards the chimney, where they part with their heat to the checkerwork in such manner that the highest degree of heat is imparted to the upper layers, and that the gaseous products reach the chimney comparatively cool (about 300° F.) After going on in this way for half-an-hour, the currents are reversed by means of suitable reversing valves, and the cold air and combustible gas now enter the furnace chamber, after having taken up heat from the regenerator in the reverse order in which it was deposited, reaching the furnace therefore nearly at the temperature at which the gases of combustion left the same. A great reversion of temperature within the chamber is the result, and the two first-mentioned regenerators are heated to a higher degree than the latter. It is easy to conceive that in that way, heat may be accumulated within the chamber to an apparently unlimited extent, and with a minimum of chimney draught.

Practically the limit is reached at the point where the materials composing the chamber begin to melt. Whereas a theoretical limit also exists in the fact that combustion ceases at a point which has been laid by St. Clair Deville at 5000° Fah., and which has been called by him the point of dissociation. At this point hydrogen might be mixed with oxygen and yet the two would not combine, showing that combustion really only takes place between the units of temperature of about 500° and 4,500° Fah.

To return to the regenerative gas-furnace. It is evident that there must be economy where, within ordinary limits, any degree of heat can be obtained, while the products of combustion pass in the chimney only 300° hot. Practically a ton of steel is melted in this furnace with 12 cwt. of small coal consumed in the gas-producer, which latter may be placed at any reasonable distance from the furnace, and consists of a brick chamber containing several tons of fuel in a state of slow disintegration. In large works, a considerable number of these gas-producers are connected by tubes or flues with a number of furnaces. Collateral advantages in this system of heating, which is now extensively used in this and other countries, are that no smoke is produced, and that the works are not encumbered with solid fuel and ashes.

It is a favourite project of mine, which I have not had an opportunity yet of carrying practically into effect, to place these gas-producers at the bottom of coal-pits. A gas shaft would have to be provided to conduct the gas to the surface, the lifting of coal would be saved, and the gas in its ascent would accumulate such an amount of forward pressure that it might be conducted to a distance of several miles to the works or places or consumption. This plan, so far from being dangerous, would insure a perfect ventilation of the mine, and would enable us to utilise those waste deposits of small coal (amounting on the average to 20 per cent.) which are now left unutilised within the mine.

Another plan of the future which has occupied my attention is the supply of towns with heating gas for domestic and manufacturing purposes. In the year 1863 a company was formed, with the concurrence of the corporation of Birmingham, to provide such a supply in that town at the rate of 6*d*. per 1,000 cubic feet: but the Bill necessary for that purpose was thrown out in the Committee of the House of Lords because their Lordships thought that if this was as good a plan as it was represented to be, the existing gas companies would be sure to carry it into effect. I need hardly say that the existing companies have not carried it into effect, having been constituted for another object, and that the realisation of the plan itself has been indefinitely postponed.

Coal Question.—Having now passed in review the principal applications of fuel, with a view chiefly to draw the distinction between our actual consumption and the consumption that would result if our most approved practice was made general; and having, moreover, endeavoured to prove to you which are the ultimate limits of consumption which are absolutely fixed by theory, but which we shall never be able to realise completely, I will now apply my reasoning to the coal question of the day.

In looking into the "Report of the Select Committee appointed to Inquire into the Causes of the present Dearness of Coal," we find that in 1872 no less than 123,000,000 tons of coal were got up from the mines of England and Wales, notwithstanding famine prices and the colliers' strikes. In 1862 the total getting of coal amounted to only 83,500,000, showing a yearly average increase of consumption of 4,000,000 tons. If this progressive increase continues, our consumption will have reached, thirty years hence, the startling figure of 250,000,000 tons per annum, which would probably result in an increase of price very much in excess of limits yet reached. In estimating last year's increase of price, which has every appearance of being permanent, at 8*s*. per ton all round, and after deducting the 13,000,000 tons which were exported abroad, we find that the British consumer had to pay 44,000,000*l*. more than the market value of former years for his supply of coal—a sufficient sum, one would think, to make him look earnestly into the question of "waste of fuel," which, as I shall presently be able to show, is very great indeed. The Select Committee just quoted sums up its report by the following expression :—"The general conclusion to be drawn from the whole evidence is, that though the production of coal increased in 1872 in a smaller ratio than it had increased in the years immediately preceding, yet if an adequate supply of labour can be obtained, the increase of production will shortly keep pace with that of the last few years."

This is surely a very insufficient conclusion to be arrived at by a Select Parliamentary Committee after a long and expensive inquiry, and the worst of it is, that it stands in direct contradiction with the corrected table given in the same report, which shows that the progressive increase of production has been fully maintained during the last two years, having amounted to 5,826,000 for 1871, and 5,717,000 for 1872; whereas the average increase during the last ten years has only been 4,000,000 tons. It is to be hoped that Parliament will not rest satisfied with such a negative result, but will insist to know what can be done to re-establish a proper balance between demand and supply of coal in preventing its conversion into smoke or other equally hurtful or useless forms of energy.

In taking the 105 million tons of coal consumed in this country last year for our basis, I estimate that, if we could make up our minds to consume our coal in a careful and judicious manner, according to our present lights, we should be able to reduce that consumption by 50 million tons. The realisation of such an economy would certainly involve very considerable expenditure of capital, and must be a work of time, but what I contend is that our progress in effecting economy ought to be accelerated in order to establish a balance between the present production and the ever-increasing demand for the effects of heat.

In looking through the statistical returns of the progressive increase of population, of steam power employed, and of production of iron and steel, &c., I find that our necessities increase at a rate of not less than 10 per cent. per annum, whereas our coal consumption increases only at the rate of 4 per cent, showing that the balance of 6 per cent. is met by what may be called our "intellectual progress." Now considering the enormous margin for improvement before us, I contend that we should not rest satisfied with this rate of intellectual progress, which involves an annual deficit of 4,000,000 tons to be met by increased coal consumption, but that we should bring our intellectual progress up to the rate of our industrial progress, by which means we should make the coal production nearly a constant quantity for several generations to come; by which time our successors may be expected to have effected another great step in advance towards the theoretical limit of effect, which, as we have seen, lays so far above any actual result which we have as yet attained to, that an annual consumption of 10 million tons would give more than the equivalent of the heat energy which we actually consume,

Solar Heat.—I have endeavoured to show, in the early part of this lecture, that all available energy upon the earth, excepting the tidal wave, is derived from the sun, and that the amount of heat radiated year by year, could be measured by the evaporation of a layer of water 14 ft. thick, spread over the entire surface, which again would be represented by the combustion of a layer of coal, covering our entire globe, 1 ft. in thickness. The amount of heat radiated away from the sun would be represented by the annual combustion of a thickness of coal 17 miles thick, covering its entire surface, and it has been a source of wonderment with natural philosophers how so prodigious an amount of heat could be given off year after year without any appreciable diminution of the sun's heat having become observable.

Recent researches with the spectroscope, chiefly by Norman Lockyer, have thrown much light upon this question. It is now clearly made out that the sun consists near the surface, if not throughout its mass, of gaseous elementary bodies, and in a great measure of hydrogen gas, which cannot combine with the oxygen present, owing to great elevation of temperature (due to the original great compression) which has been estimated at from 20,000° to 22,000° Fah. This chemically inert and comparatively dark mass of the sun is surrounded by the photosphere where the gaseous constituents of the sun rush into combustion, owing to reduction of temperature in consequence of their expansion and of radiation of heat into space; this photosphere is surrounded in its turn by the chromosphere, consisting of the products of combustion, which, after being cooled down through further loss of heat by radiation, sink back, owing to their acquired density, towards the centre of the sun, where they become again intensely heated through compression and are dissociated or split up again into their elements at the expense of internal solar heat. Great convulsions are thus continually produced upon the solar surface, resulting frequently in explosive actions of extraordinary magnitude, when masses of living fire are projected a thousand miles or more upward, giving rise to the phenomena of sun-spots and of the corona which is visible during the total eclipses of the sun. The sun may therefore be looked upon in the light of a gigantic gas-furnace, in which the same materials of combustion are used over and over again.

It would be impossible for me at this late hour to enter deeper upon speculations regarding the "regeneration of the sun's heat upon its surface," which question is replete with scientific and also practical interest, because Nature is our safest teacher, and in comprehending the great works of our Creator we shall learn how to utilise to the best advantage those stores of potential energy in the shape of coal which have providentially been placed at our disposal.

COALS AND COAL PLANTS *

PROF. WILLIAMSON said that his distinguished friend, their president, had spoken the truth to a certain extent; but at the same time there was in what he had said a slight measure of what a particular school would call the *suggestio falsi*. He believed that if a balance of account could be struck between them it would be found that he (the lecturer) was enormously the gainer from the fact that he enjoyed the same name as the president. As far as he could arrange the balance it was this—that their president was debtor one dinner which he (the lecturer) always contended his friend had got because he had received a card of invitation which did not belong to him—while, on the other hand, there was an item of credit to the extent of all the learning the president displayed at every meeting of the British Association, but for which, at least in the North of England, he (Prof. W. C. Williamson) was usually credited. Under these circumstances he thought it would be seen that instead of his being the loser he was in reality an enormous gainer.

He remembered a distinguished friend of his, a member of the House of Commons, telling him that whenever an individual rose in that house to speak on a subject on which he was known to have written a book, the house speedily became emptied, because the members were alarmed at the idea of a speech from a man who had an inveterate hobby. He presumed, however, that he stood there that night simply because he had a hobby; but he would promise not to ride it too far or inflict it too long upon his audience. Furthermore when he remembered how short was the time since Prof. Huxley had addressed a Bradford audience on the subject of coal, he was somewhat appalled at his own boldness in having ventured to deal with a similar matter at the present moment. But luckily for him science did not stand still, and although so short a time had elapsed since Prof. Huxley had delivered the lecture referred to, there was much now to be said on the subject which could not have been said then. Still, with the magnificent address of Prof. Huxley within reach, it would not be necessary to detain the auditory long on the general theories which were now so widely accepted with reference to the origin of coal.

Prof. Phillips, in his address to the Geological Section on the previous morning, had reminded them how short a time it was—the period being within his own life-time—since the vegetable origin of coal was broadly and openly disputed. It would, however, be difficult now to find any one at all enlightened on the subject who would venture to dispute that the origin of coal was vegetable. In the same way another hypothesis—known by the title of the drift theory—had once been very generally accepted. Men who admitted the conclusion that coal had once been a mass of vegetable life differed as to the method by which that vegetable mass had found its way into its present position. The majority of the older geologists believed that coal had been conveyed into those positions by water—that large quantities of vegetable material had been brought down great rivers like the Mississippi or the Ganges, that these vegetable rafts, as they might be termed, had accumulated in the estuaries and the ocean, and that when they had become thoroughly water-logged, they had sunk to the bottom and formed accumulations of vegetable elements sufficient to constitute the existing coal-beds. Thanks to the labours of a series of indefatigable workers like the late Mr. Bowman, Mr. Binney, Sir Wm. Logan, and others, we now had a clearer and much more probable conception as to what coal originally was.

It must be understood that although the earth was popularly regarded as the type of everything that was stable and immovable, this was a very erroneous idea; for old mother earth was about one of the most fickle and inconstant of all the jades with which men had deal. She was never still. It happened that at the present day there were certain regions, such as the volcanic regions, which were always moving upwards, like the more aspiring of the youths of Bradford, while there were others, such as the coral regions, which were steadily going downward, like those less fortunate youths who did not succeed in the race of life. So it had been in the olden time. The coal beds appeared to have accumulated in the latter class of areas—the areas of depression—geographical areas in which the earth had a tendency to sink below the level of the ocean. Upon such areas mud and silt had accumulated until the deposit thus formed had reached the level of the water, and then came what would appear to have been highly necessary as a preliminary to the growth of the coal material, namely, a bed of blue mud. It was not known why that blue mud was there or whence it came, but it was as certain as that garden plants required favourable soils for their development, that whatever its cause the blue mud was the soil which seemed to have been preferred by the great majority of the plants constituting the forests of the carboniferous era. In it the minute spores or seeds of the vegetables which afterwards became coal, germinated and struck root, until eventually the muddy soil became converted into a magnificent and almost tropical forest. As the forest grew the spores fell from the trees, the half-dead leaves and decayed branches also dropped, and by-and-by the stems themselves gave way, and thus was accumulated an immense amount of vegetable matter. This, in the progress of time, sank below the water level, and more mud being deposited on the top of the coal, the new formation in turn underwent the same processes as its predecessors, until at length a new forest was formed to share the same fate as that which had gone before it. The process was repeated again and again, until at length we had an accumulation of materials, mixtures of the various substances he had spoken of, alternating with beds of coal, until we had a vertical thickness of rock varying from three, four, or five, to as much as eight or ten thousand feet.

But while these general truths were accepted with little or no reservation, there were one or two points contained in Prof. Huxley's lecture upon which he would venture for a moment to dwell. In that lecture he properly laid stress upon certain minute bodies that were found in the interior of coal.

[The lecturer here pointed to a diagram representing a vertical

* Abstract of Lecture delivered before the British Association, at Bradford, by Prof. W. C. Williamson, F.R.S.

section of coal, and he also exhibited various pieces of coal, one of which he held in the position it occupied in the coal bed. Another diagram, he said, represented a quantity of black coaly matter arranged in layers, and embedded in this matter were some small bodies which had been flattened by the pressure of the coal, and by the superimposed beds between the coal.]

Prof. Huxley spoke of these bodies under the name of sporangia, or spore cases. Now, he (Prof. Williamson) had come to the conclusion that they were all spores of two classes—the larger ones called macro-spores, and the smaller ones micro-spores. A large number of the plants, if not all, found in the coal-measures belonged to the cryptogamic plants, in which was found no trace of seeds or flowers. The reproductive bodies that took the place of seeds were little bud-like structures, to which the name of spores was given. In a certain class of those plants, the club-mosses, for instance, were two kinds of these spores. The sporangia of club mosses and similar plants never became detached from their parent stem. They burst and liberated multitudes of contained spores, which were objects like those so abundant in many coals. But these spores did not play so important a part in the formation of coal as Prof. Huxley supposed. On examining these objects it was found that each of the little rounded discs exhibited three ridges that radiated in a triangular manner from a common centre. These discs were originally masses of protoplasm, lodged within a mother-cell. By-and-by each of these masses broke up into three or four parts; and it was found that to accommodate one another in the interior of their circular chamber, they mutually pressed one another. To illustrate the mutual compression, Prof. Williamson produced a turnip, which he had cut into four parts, that corresponded exactly, he said, in their arrangement with the arrangement of the four spores in the interior of the mother cell.

Then Prof. Huxley held that coal consisted of two elements. Prof. Williamson, exhibiting again a piece of coal said the dirty blackening surface was a thin layer of little fragments of woody structures, vegetable tissues of various kinds, known by the name of mineral charcoal. These layers of mineral charcoal were exceedingly numerous. Prof. Huxley, recognising the abundance and significance of these little spore-like bodies, thought that mineral charcoal formed only a portion, and a limited portion, while the great bulk of black coaly matter was really a mass of carbon derived from chemically altered spores. He thought that on this point they would be obliged somewhat to differ from Prof. Huxley.

The bed which had been most widely quoted as containing most beautiful spores was found in the district of Bradford. If everything decayed, and Bradford was by an exceedingly improbable combination of circumstances to pass out of memory, it would be remembered in scientific history as the locality in which the "better bed" was found. The fragment he held in his hand was a fragment of the better bed. On examining it for a moment through a magnifying glass he saw that it was a solid mass of mineral charcoal, yet the microscope revealed in it no trace whatever of organic structure. Therefore, while Prof. Huxley divided coal into two elements—mineral charcoal and coal proper, including in the latter term altered spores—he would say that coal consisted of three elements—mineral charcoal, black coal derived from mineral charcoal, and spores.

This outline of the history of coal led them to the independent conclusion that two elements were mingled in coal; the vegetable *débris*, or broken up fragments of the plants of the carboniferous age were intermingled with the peculiar spores to which Prof. Huxley had so properly called attention. In proceeding to deal further with the plants of which coal was formed, the lecturer took occasion to acknowledge with thanks the loan of certain valuable specimens to illustrate his discourse from the Bradford Museum. One of these specimens was a most rare and valuable specimen which he would be glad to take away with him to Owens College, if he had the chance; but he was afraid the Bradford people were too Conservative to stand that.

After giving a number of botanical and other details with regard to the plants of which coal was formed, he said our knowledge of this subject resolved itself into two divisions, viz., that of the outward forms of plants and that of their inward organisation. These two lines of inquiry did not always run parallel, and the one great object of recent research had been to make them do so. Specimens throwing light on the subject had been found at Arran, Burntisland, Oldham, Halifax, Autun in France, and elsewhere, and upon these a host of observers had been and still were working. It had long been known that most, if not all, the coal plants belonged to two classes, known as the Cryptogamia, or flowerless plants, and the gymnospermous exogens, represented by the pines and firs. All recent inquiries added fresh strength to this conclusion. One of the most important of these groups was that of the Equiseta or horse tails, and which were represented in the coal by the Calamites. The long cylindrical stems, with their transverse joints and longitudinal grooves, were shown to be casts of mud or sand, occupying the hollows in the piths of the living plants. Each of these piths was surrounded by a thick zone of wood, which again was invested by an equally thick layer of bark. Specimens were shown in which, though the pith was only an inch in diameter, the wood and bark combined formed a cylinder 4 inches thick, giving a circumference of at least 27 inches to the living stem. But there exist examples of the pith casts alone, which are between 2 and 3 feet in diameter. It was evident, therefore, he concluded, that the Calamites became true forest trees, very different from their living representatives—the horse tails of our ponds and marshes.

After describing the organisation of these plants, the Professor proceeded to describe the Lycopods of the coal measures as represented by the Lepidodendra, Sigillariæ, and a host of other well-known plants. The living Lycopods, whether seen at home or in tropical forests, are dwarf herbaceous plants, but in the carboniferous age they became lofty forest trees, 100 feet high, and ten or twelve feet in circumference. To enable such lofty stems, with their dense mass of serial branches and foliage, to obtain nutrition, an organisation was given to them approaching more nearly to that of our living forest trees than to that of any recent cryptogams. A succession of woody layers was added to the exterior of those previously existing; so that as the plant rose into the air the stem became strengthened by these successive additions to the vascular tissue. As this process advanced it was accompanied by other changes, producing a large central pith, and two independent vascular rings immediately surrounding the pith, and the relations of these various parts to the roots, and leaves, as well as to the nutrition of the plants, was pointed out. The fruits of these Lycopods were then examined. The existence of two classes of spores corresponding in functions to the stamens and pistils of flowering plants, was dwelt upon, and one of these classes (the macrospores) was shown to be so similar to the small objects found in coal, as to leave no doubt that those objects were derived from the lepidodendroid and sigillarian trees which constituted the large portion of the forest vegetation.

Certain plants known as Asterophyllites were next examined. The ferns were also reviewed, and shown to be as remarkable for the absence of exogenous growth from their stems as the Calamites and Lycopods were for its conspicuous presence. The structure of some stems supposed to represent palms was shown to be that of a fern, there being no true evidence that palms existed in that age. The plants known as coniferous plants, allied to pines and firs, were described, and their peculiar fruits, so common at Peel, in Lancashire, were explained, and some plants of unknown affinities, but beautiful organisation, were referred to. The physiological differences between these extinct ferns, and other plants especially in their marvellous *quasi*-exogenous organisation, was pointed out, and the lecturer concluded by showing how unvarying must have been the green hue of the carboniferous forests, owing to the entire absence from them of all the gay colours of the flowering plants which form so conspicuous a feature in the modern landscape, especially in the temperate and colder regions. The antiquity of the mummy, he added, was as nothing compared with the countless ages that had rolled by since these plants lived, and yet they must not forget that every one of those plants, living in ages so incalculably remote, had a history, an individuality as distinct and definite as our own. They would probably be inclined to ask the question, When did all these things take place? Echo answered, When?

THE BRITISH ASSOCIATION

THE Bradford Meeting has been on the whole a good one; though there have been no salient discussions, the papers read have been all up to a good useful average. Mr. Ferrier's paper on the brain was a surprise to many, we believe, and the only approach to a genuine sensation was the appearance of Captain Markham, R.N., in the Geographical Section

on Saturday, he having arrived only the previous day at Dundee in the *Arctic*, along with the *Polaris* men.

The private hospitality of the Bradfordians has been magnificent, but the hotel charges, every one admits, have been simply monstrous. We quite agree with the remarks made in the last number of the *Pharmaceutical Journal* on this subject, and do not think that hotel-keepers by so recklessly increasing their ordinary charges do themselves or their town any good. We hope that in future the authorities of towns visited by the British Association will devise some means of counteracting such proceedings, as they no doubt tend to diminish the number of visitors. The number of tickets of all classes issued this year is not much above 1,800, being several hundreds under that of last year; no doubt the relative attractions of Brighton and Bradford will partly account for this.

The *soirée* in St. George's Hall last Thursday was a great success; indeed all the arrangements for the meeting have been satisfactory. The public lectures, by Profs. W. C. Williamson, Clerk-Maxwell, and Dr. Siemens were well attended, but the proportion of the working-classes present at the lecture on Fuel, which was specially intended for their benefit, was very small. Indeed, many are of opinion that this lecture should be abolished, seeing that so few workpeople take advantage of it, and that a lecture should be given every night, or three or four times during the meeting, to working-men who are registered, as at the School of Mines, in order to secure that the right sort of people gain admission.

This year the Association gave another lesson to Government. Last year, it may be remembered, the question of the Tides was given up by the Association; this year they have done the same to the Rainfall question, as being a work which it is the interest of the nation to see done. We hope the nation will see that it is attended to in the proper quarter.

On Monday Prof. Smith proposed Dr. Tyndall as president of next year's meeting; and it was somewhat of a surprise to most present when the Mayor of Belfast patriotically proposed that Prof. Andrews of that city should preside over a meeting to be held in Ireland. Prof. Andrews had been first suggested by the Council, and his friends were consulted, but it was found that the state of his health rendered it unadvisable to press the honour upon him.

Belfast is the place of meeting next year, and Bristol, it has been settled, will be visited by the Association in 1875; there is a tacit understanding that Glasgow will be the rendezvous for 1876, the Lord Provost and a strong deputation being present on Monday to earnestly urge the claims of that important place.

The Report of the Council for the year 1872-3 was presented to the General Committee at Bradford, on Wednesday, 17th September. The Council have had under their consideration the three Resolutions which were referred to them by the General Committee at Brighton. The first Resolution was—"That the Council be requested to take such steps as they deem desirable to induce the Colonial Office to afford sufficient aid to the Observatory at Mauritius to enable an investigation of the cyclones in the Indian Ocean to be carried on there."

In accordance with this Resolution, a correspondence took place between Dr. Carpenter, the President of the Association, and the Right Honourable the Earl of Kimberley, Secretary of State for the Colonies.

In consequence of this correspondence, the Council requested the President to urge upon the Lords Commissioners of Her Majesty's Treasury the desirability of affording such pecuniary aid to the Mauritius Observatory as would enable the Director to continue his observations on the periodicity of the cyclones; and an intimation has been received from Her Majesty's Government that an inquiry into the condition, size, and cost of the establishment of the Mauritius is now being conducted by a Special Commission from England, pending which inquiry no increase of expenditure upon the Observatory can be sanctioned; but that when the results of this inquiry shall be made known, the Secretary of State for the Colonies will direct the attention of the Governor to the subject.

The second Resolution referred to the Botanical establishment at Kew, but happily the Council have not deemed it necessary to take any action upon this Resolution.

Third Resolution:—"That the Council be requested to take such steps as they may deem desirable to urge upon the Indian Government the preparation of a Photoheliograph and other instruments for solar observation, with the view of assisting in the observation of the Transit of Venus in 1874, and for the continuation of solar observations in India."

The Council communicated with his Grace the Duke of Argyll, the Secretary of State for India, upon the subject, with the result explained in the following letter:—

"India Office, February 28, 1873.

"Sir,—With reference to my letter of the 13th of December last, relative to an observation in India of the Transit of the planet Venus in December 1874, I am directed to state, for the information of the Council of the British Association for the Advancement of Science, that the Secretary of State for India in Council, having reconsidered this matter, and looking to the number of existing burdens on the revenues of India, and to the fact that the selection of any station in that country was not originally contemplated for 'eye-observations' of the transit, has determined to sanction only the expenditure (356*l.* 7*s.* 6*d.*) necessary for the purchase and packing of a Photoheliograph, and any further outlay that may be requisite for the adaptation of such instruments as may be now in India available for the purpose of the proposed observation.

"The Duke of Argyll in Council has been led to sanction thus much of the scheme proposed by Lieut. Colonel Tennant, in consequence of the recommendation submitted by the Astronomer Royal in favour of the use of photography for an observation of the transit at some place in Northern India.

"I am, Sir, Your obedient Servant,

(Signed) "Herman Merivale."

"William B. Carpenter, Esq., British Association."

A Committee was appointed at Exeter in 1869, on the Laws Regulating the Flow and Action of Water holding Solid Matter in Suspension, with authority to represent to the Government the desirability of undertaking Experiments bearing on the subject. The Committee presented a Memorial to the Indian Government, who have recently intimated their intention of advancing a sum of 2,000*l.* to enable Mr. Login to carry on experiments.

The Council have added the following list of names of gentlemen present at the last meeting of the Association to the list of Corresponding Members: M. C. Bergeron, Lausanne; Prof. E. Croullebois, Paris; Prof. G. Devalque, Liège; M. W. De Fonvielle, Paris; Prof. Paul Gervais, Paris; Prof. James Hall, Albany, New York; Mr. J. E. Hilgard, Coast Survey, Washington; M. George Lemoine, Paris; Prof. Victor von Richter, St. Petersburg; Prof. Carl Semper, Wurtzburg; Prof. A. Wurtz, Paris.

We now pass on at once to the Sectional work, delaying a reference to the Scientific grants made this year, and the concluding business till next week.

SECTION A.

Opening Address by the President, Prof. Henry J. S. Smith, M.A., LL.D., F.R.S.

For several years past it has been the custom for the president of this section, as of the other sections of the Association, to open its proceedings with a brief address. I am not willing upon this occasion to deviate from the precedent set by my predecessors, although I feel that the task presents peculiar diffi-

culties to one who is by profession a pure mathematician, and who, in other branches of science, can only aspire to be regarded as an amateur.

But, although I thus confess myself a specialist, and a specialist it may be said of a narrow kind, I shall not venture, in the few remarks which I now propose to make, to indulge my own speciality too far.

I am well aware that we are certain, in this section, to have a sufficient number of communications, which of necessity assume a special and even an abstruse character, and which, whatever pains may be taken to give them clearness, and however valuable may be the results to which they lead, are nevertheless extremely difficult to follow, not only for a popular audience, but even for men of science whose attention has not been specially, and recently, directed to the subject under discussion. I should think it, therefore, almost unfair to the section, if at the very commencement of its proceedings I were to attempt to direct its attention in any exclusive manner to the subject which, I confess, if I were left to myself, I should most naturally have chosen—the history of the advances that have been made during the last ten or twenty years in mathematical science. Instead, therefore, of adventuring myself on this difficult course, which, however, I strongly recommend to some successor of mine less scrupulous than myself, I propose, though at the risk of repeating what has been better said by others before me, to offer some general considerations which may have a more equal interest for all those who take part in the proceedings of this section, and which appear to me at the present time to be more than usually deserving of the notice of those who desire to promote the growth of the scientific spirit in this country. I intend, therefore, while confining myself as strictly as I can to the range of subjects belonging to this section, to point out one or two, among many, of the ways in which sectional meetings, such as ours, may contribute to the advancement of science.

We all know that Section A of the British Association is the section of mathematics and physics; and I dare say that many of us have often thought how astonishingly vast is the range of subjects which we slur over, rather than sum up, in this brief designation. We include the most abstract speculations of pure mathematics, and we come down to the most concrete of all phenomena—the most every-day of all experiences. I think I have heard in this section a discussion on spaces of five dimensions, and we know that one of our committees, a committee which is of long-standing, and which has done much useful work, reports to us annually on the Rainfall of the British Isles. Thus our wide range covers the mathematics of number and quantity in their most abstract forms, the mathematics of space, of time, of matter, of motion, and of force, the many sciences which we comprehend under the name of astronomy, the theories of sound, of light, heat, electricity; and besides the whole physics of our earth, sea, and atmosphere, the theory of earthquakes, the theory of tides, the theory of all the movements of the air, from the lightest ripple that affects the barometer up to a cyclone. As I have already said, it is impossible that communications on all these subjects should be interesting, or indeed intelligible, to all our members; and, notwithstanding the pains taken by the committee and by the secretaries to classify the communications offered to us, and to place upon the same days those of which the subjects are cognate to one another, we cannot doubt that the disparateness of the material which comes before us in this section is a source of serious inconvenience to many members of the Association. Occasionally, too, the pressure upon our time is very great, and we are obliged to hurry over the discussions on communications of great importance, the number of papers submitted to us being, of course, in a direct proportion to the number of the subjects included in our programme. It has again and again been proposed to remedy these admitted evils by dividing the section, or at least by resolving it into one or more sub-sections. But I confess that I am one of those who have never regretted that this proposal has not commended itself to the Association, or indeed to the section itself. I have always felt that by so sub-dividing ourselves we should run the risk of losing one or two great advantages which we at present possess; and I will briefly state what, in my judgment, these advantages are.

I do not wish to undervalue the use to a scientific man of listening to and taking part in discussions on subjects which lie wholly in the direction in which his own mind has been working. But I think, nevertheless, that most men who have attended a meeting of this Association, if asked what they have chiefly gained by it, would answer in the first place that they have had opportunities of forming or of renewing those acquaintances or intimacies with other scientific men which, to most men engaged in scientific pursuits, are an indispensable condition of successful work; and in the second place, that while they may have heard but little relating to their own immediate line of inquiry which they might not as easily have found in Journals or Transactions elsewhere, they have learned much which might otherwise have never come to their knowledge of what is going on in other directions of scientific inquiry, and that they have carried away many new conceptions, many fruitful germs of thought, caught perhaps from a discussion turning upon questions apparently very remote from their own pursuits. An object just perceptible on a distant horizon is sometimes better descried by a careless sideward glance than by straining the sight directly at it; and so capricious a gift is the inventive faculty of the human mind that the clue to the mystery hid beneath some complicated system of facts will sometimes elude the most patient and systematically conducted search, and yet will reveal itself all of a sudden upon some casual suggestion arising in connection with an apparently remote subject. I believe that the mixed character and wide range of our discussions has been most favourable to such happy accidents. But even apart from these, if the fusion in this section of so many various branches of human knowledge tends in some degree to keep before our minds the essential oneness of science, it does us a good service. There can be no question that the increasing specialisation of the sciences, which appears to be inevitable at the present time, does nevertheless constitute one great source of danger for the future progress of human knowledge. This specialisation is inevitable, because the further the boundaries of knowledge are extended in any direction, the more laborious and time-absorbing a process does it become to travel to the frontier; and thus the mind has neither time nor energy to spare for the purpose of acquainting itself with regions that lie far away from the track over which it is forced to travel. And yet the disadvantages of excessive specialisation are no less evident, because in natural philosophy, as indeed in all things on which the mind of man can be employed, a certain wideness of view is essential to the achievement of any great result, or to the discovery of anything really new. The twofold caution so often given by Lord Bacon against over-generalisation on the one hand, and against over-specialisation on the other, is still as deserving as ever of the attention of mankind. But in our time, when vague generalities and empty metaphysics have been beaten once, and we may hope for ever, out of the domain of exact science, there can be but little doubt on which side the danger of the natural philosopher at present lies. And perhaps in our section, as at present constituted, there is a freer and fresher air—we are, perhaps, a less inadequate representation of "that greater and common world" of which Lord Bacon speaks, than if we were subdivided into as many parts as we include—I will not say sciences—but groups of sciences. Perhaps there is something in the very diversity and multiplicity of the subjects which come before us which may serve to remind us of the complexity of the problems of science, of the diversity and multiplicity of nature.

On the other hand it is not, as it seems to me, difficult to assign the nature of the unity which underlies the diversity of our subjects, and which justifies, to a very great extent, the juxtaposition of them in our section. That unity consists not so much in the nature of the subjects themselves, as in the nature of the methods by which they are treated. A mathematician, at least—and it is as a mathematician I have the privilege of addressing you—may be excused for contending that the bond of union among the physical sciences is the mathematical spirit and the mathematical method which pervades them. As has been said with profound truth by one of my predecessors in this chair, our knowledge of nature, as it advances, continuously resolves differences of quality into differences of quantity. All exact reasoning —indeed all reasoning—about quantity is mathematical reasoning; and thus as our knowledge increases, that portion of it which becomes mathematical increases at a still more rapid rate. Of all the great subjects which belong to the province of this section, take that which at first sight is the least within the domain of mathematics—I mean meteorology. Yet the part which mathematics bears in meteorology increases every year, and seems destined to increase. Not only is the theory of the simplest instruments of meteorology essentially mathematical, but the discussion of the observations—upon which, be it remembered, depend the hopes which are already entertained with increasing confidence, of reducing the most variable and complex of all known phenomena to exact laws—is a problem which

not only belongs wholly to mathematics, but which taxes to the utmost the resources of the mathematics which we now possess. So intimate is the union between mathematics and physics that probably by far the larger part of the accessions to our mathematical knowledge have been obtained by the efforts of mathematicians to solve the problems set to them by experiment, and to create "for each successive class of phenomena, a new calculus or a new geometry, as the case might be, which might prove not wholly inadequate to the subtlety of nature." Sometimes, indeed, the mathematician has been before the physicist, and it has happened that when some great and new question has occurred to the experimentalist or the observer, he has found in the armoury of the mathematician the weapons which he has needed ready made to his hand. But, much oftener, the questions proposed by the physicist have transcended the utmost powers of the mathematics of the time, and a fresh mathematical creation has been needed to supply the logical instrument requisite to interpret the new enigma. Perhaps I may be allowed to mention an example of each of these two ways in which mathematical and physical discovery have acted and re-acted on each other. I purposely choose examples which are well known and belong, the one to the oldest, the other to the latest times of scientific history.

The early Greek geometers, considerably before the time of Euclid, applied themselves to the study of the various curve lines, in which a conical figure may be cut by a plane—curve lines to which they gave the name, never since forgotten, of conic sections. It is difficult to imagine that any problem ever had more completely the character of a "problem of mere curiosity," than this problem of the conic sections must have had in those earlier times. Not a single natural phenomenon which in the state of science at that time could have been intelligently observed was likely to require for its explanation a knowledge of the nature of these curves. Still less can any application to the arts have seemed possible; a nation which did not even use the arch were not likely to use the ellipse in any work of construction. The difficulties of the inquiry, the pleasure of grappling with the unknown, the love of abstract truth, can alone have furnished the charm which attracted some of the most powerful minds in antiquity to this research. If Euclid and Apollonius had been told by any of their contemporaries that they were giving a wholly wrong direction to their energies, and that instead of dealing with the problems presented to them by nature were applying their minds to inquiries which not only were of no use, but which never could come to be of any use, I do not know what answer they could have given which might not now be given with equal, or even with greater justice, to the similar reproaches which it is not uncommon to address to those mathematicians of our own day who study quantics of n-indeterminates, curves of the nth order, and (it may be) spaces of n-dimensions. And not only so, but for pretty nearly two thousand years, the experience of mankind would have justified the objection: for there is no record that during that long period which intervened between the first invention of the conic sections and the time of Galileo and Kepler, the knowledge of these curves possessed by geometers was of the slightest use to natural science. And yet, when the fulness of time was come, these seeds of knowledge, that had waited so long, bore splendid fruit in the discoveries of Kepler. If we may use the great names of Kepler and Newton to signify stages in the progress of human discovery, it is not too much to say that without the treatises of the Greek geometers on the conic sections there could have been no Kepler, without Kepler no Newton, and without Newton no science in our modern sense of the term, or at least no such conception of nature as now lies at the basis of all our science, of nature as subject in its smallest as well as in its greatest phenomena, to exact quantitative relations, and to definite numerical laws.

This is an old story; but it has always seemed to me to convey a lesson, occasionally needed even in our own time, against a species of scientific utilitarianism which urges the scientific man to devote himself to the less abstract parts of science, as being more likely to bear immediate fruit in the augmentation of our knowledge of the world without. I admit, however, that the ultimate good fortune of the Greek geometers can hardly be expected by all the abstract speculations which, in the form of mathematical memoirs, crowd the Transactions of the learned societies; and I would venture to add that, on the part of the mathematician there is room for the exercise of good sense, and, I would almost say, of a kind of tact, in the selection of those branches of mathematical inquiry which are likely to be conducive to the advancement of his own or any other science.

I pass to my second example, of which I may treat very briefly. In the course of the present year a treatise on electricity has been published by Prof. Maxwell, giving a complete account of the mathematical theory of that science, as we owe it to the labours of a long series of distinguished men, beginning with Coulomb and ending with contemporaries of our own, including Prof. Maxwell himself. No mathematician can turn over the pages of these volumes without very speedily convincing himself that they contain the first outlines (and something more than the first outlines) of a theory which has already added largely to the methods and resources of pure mathematics, and which may one day render to that abstract science services no less than those which it owes to astronomy. For electricity now, like astronomy of old, has placed before the mathematician an entirely new set of questions, requiring the creation of entirely new methods for their solution, while the great practical importance of telegraphy has enabled the methods of electrical measurement to be rapidly perfected to an extent which renders their accuracy comparable to that of astronomical observations, and thus makes it possible to bring the most abstract deductions of theory at every moment to the test of fact. It must be considered fortunate for the mathematicians that such a vast field of research in the application of mathematics to physical inquiries should be thrown open to them, at the very time when the scientific interest in the old mathematical astronomy has for the moment flagged, and when the very name of physical astronomy, so long appropriated to the mathematical development of the theory of gravitation, appears likely to be handed over to that wonderful series of discoveries which have already taught us so much concerning the physical constitution of the heavenly bodies themselves.

Having now stated, from the point of view of a mathematician, the reasons which appear to me to justify the existence of so composite an institution as Section A, and the advantages which that very compositeness sometimes brings to those who attend its meetings, I wish to refer very briefly to certain definite services which this section has rendered and may yet render to Science. The improvement and extension of scientific education is to many of us one of the most urgent questions of the day; and the British Association has already exerted itself more than once to press the question on the public attention. Perhaps the time has arrived when some further efforts of the same kind may be desirable. Without a rightly organised scientific education we cannot hope to maintain our supply of scientific men; since the increasing complexity and difficulty of science renders it more and more difficult for untaught men, by mere power of genius, to force their way to the front. Every improvement, therefore, which tends to render scientific knowledge more accessible to the learner, is a real step towards the advancement of science, because it tends to increase the number of well qualified workers in science.

For some years past this section has appointed a committee to aid in the improvement of geometrical teaching in this country. The report of this committee will be laid before the section in due course; and without anticipating any discussion that may arise on that report, I think I may say that it will show that we have advanced at least one step in the direction of an important and long-needed reform. The action of this section led to the formation of an Association for the improvement of geometrical teaching, and the members of that Association have now completed the first part of their work. They seem to me, and to other judges much more competent than myself, to have been guided by a sound judgment in the execution of their difficult task, and to have held, not unsuccessfully, a middle course between the views of the conservatives who would uphold the absolute monarchy of Euclid, or, more properly, of Euclid as edited by Simeon, and the radicals who would dethrone him altogether. One thing at least they have not forgotten, that geometry is nothing if it be not rigorous, and that the whole educational value of the study is lost, if strictness of demonstration be trifled with. The methods of Euclid are, by almost universal consent, unexceptionable in point of rigour. Of this perfect rigorousness his doctrine of parallels, and his doctrine of proportion, are perhaps the most striking examples. That Euclid's treatment of the doctrine of parallels is an example of perfect rigorousness, is an assertion which sounds almost paradoxical, but which I, nevertheless, believe to be true. Euclid has based his theory on an axiom (in the Greek text it is one of the postu-

lates, but the difference for our purpose is immaterial) which, it may be safely said, no unprejudiced mind has ever accepted as self-evident. And this unaxiomatic axiom Euclid has ehosen to state, without wrapping it up or disguising it,—not, for example, in the plausible form in which it has been stated by Playfair, but in its crudest shape, as if to warn his reader that a great assumption was being made. This perfect honesty of logic, this refusal to varnish over a weak point, has had its reward; for it is one of the triumphs of modern geometry to have shown that the eleventh axiom is so far from being an axiom, in the sense which we usually attach to the word, that we cannot at this moment be sure whether it is absolutely and rigorously true, or whether it is only a very close approximation to the truth. Two of those whose labours have thrown much light on this difficult theory are at present at this meeting—Prof. Cayley, and a distinguished German mathematician, Dr. Felix Klein; and I am sure of their adherence when I say that the sagacity and insight of the old geometer are only put in a clearer light, by the success which has attended the attempt to construct a system of geometry, consistent with itself, and not contradicted by experience, upon the assumption of the falsehood of Euclid's eleventh axiom.

Again, the doctrine of proportion, as laid down in the fifth book of Euclid, is, probably, still unsurpassed as a masterpiece of exact reasoning; although the cumbrousness of the forms of expression which were adopted in the old geometry has led to the total exclusion of this part of the elements from the ordinary eourse of geometrical education. A zealous defender of Euelid might add with truth that the gap thus created in the elementary teaching of mathematics has never been adequately supplied.

But after all has been said that can be said in praise of Euclid, the fact remains that the form in which the work is composed renders it unsuitable for the earlier stages of education. Euclid wrote for men; whereas his work has been used for ehildren, and it is surely no disparagement to the great geometer to suppose that after more than 2,000 years the experience of generations of teachers can suggest changes which may make his Elements, I will not say more perfect as a piece of geometry, but more easy for very young minds to follow. The difficulty of a book or subject is indeed not in itself a fatal objection to its use in education, for to learn how to overcome difficulties is one great part of education: Geometry is hard, just as Greek is hard, and one reason why Geometry and Greek are such excellent educational subjects is precisely that they are hard. But in a world in which there is so much to learn, we must learn everything in the easiest way in which it can be learnt; and after we have smoothed the way to the utmost of our power, there is sure to be enough of difficulty left. I regard the question of some reform in the teaching of elementary geometry as so completely settled by a great concurrence of opinion on the part of the most competent judges, that I should hardly have thought it necessary to direct the attention of the seetion to it, if it were not for the following reasons:—

First, that the old system of geometrical instruction still remains (with but few exceptions) paramount in our schools, colleges, and universities, and must remain so until a very great consensus of opinion is obtained in favour of some one definite text-book. It appears to me, therefore, that the duty will eventually devolve upon this section of the British Association, of reporting on the attempts that have been made to frame an improved system of geometrical education; and if it should be found that these attempts have been at last successful, I think that the British Association should lend the whole weight of its authority to the proposed ehange. I am far from suggesting that any such decision should be made immediately. The work undertaken by the Association for the improvement of geometrical teaching is still far from complete; and even when it is complete it must be left to hold its own against the criticism of all comers before it can acquire such an amount of public confidence as would justify us in recommending its adoption by the great teaching and examining bodies of the country.

Secondly, I have thought it right to remind the section of the part it has taken with reference to the reform of geometrical teaching, because it appears to me that a task, at once of less difficulty and of more immediate importance, might now be undertaken by it with great advantage. There is at the present moment a very general agreement that a eertain amount of natural science ought to be introduced into school education; and many schools of the country have already made most laudable efforts in this direction. As far as I can judge, there is further a general agreement that a good school course of natural science ought to include some part or parts of physics, of chemistry, and of biology; but I think it will be found that while the courses of chemistry given at our best schools are in the main identical, there is great diversity of opinion as to the parts of physics and of biology which should be selected as suitable for a school education, and a still greater diversity of opinion as to the methods which should be pursued in teaching them. Under these circumstances it is not surprising to find that the masters of those schools into which natural science has hardly yet found its way (and some of the largest and most important schools in the country are in this class), are doubtful as to the course which they should take; and from not knowing precisely what they should do, have not as yet made up their minds to do anything of importance. There can be no doubt that the masters of such schools would be glad on these points to be guided by the opinion of scientific men; and I cannot help thinking that this opinion would be more unanimous than is commonly supposed, and further, that no public body would be so likely to elicit an expression of it, as a Committee appointed by the British Association. I believe that if such an expression of the opinion of scientific men were once obtained, it would not only tend to give a right direction to the study of natural science in schools, but might also have the effect of inducing the public generally to take a higher and more truthful view of the objects which it is sought to attain by introducing natural science as an essential element into all eourses of education. All knowledge of natural science that is imparted to a boy, is, or may be, useful to him in the business of his after life; but the claim of natural science to a place in education cannot be rested upon its practical usefulness only. The great object of education is to expand and to train the mental faculties, and it is because we believe that the study of natural science is eminently fitted to further these two objects, that we urge its introduction into school studies. Science expands the minds of the young, because it puts before them great and ennobling objects of contemplation; many of its truths are such as a child can understand, and yet such that, while in a measure he understands them, he is made to feel something of the greatness, something of the sublime regularity, and of the impenetrable mystery, of the world in which he is placed. But science also trains the growing faculties, for science proposes to itself truth as its only object, and it presents the most varied, and at the same time the most splendid examples, of the different mental processes which lead to the attainment of truth, and which make up what we call reasoning. In science, error is always possible, often close at hand; and the constant necessity for being on our guard against it is one important part of the education which science supplies. But in science, sophistry is impossible; science knows no love of paradox; science has no skill to make the worse appear the better reason; science visits with a not long deferred exposure all our fondness for preconceived opinions, all our partiality for views that we have ourselves maintained, and thus teaches the two best lessons that ean well be taught—on the one hand the love of truth, and on the other, sobriety and watchfulness in the use of the understanding.

In accordance with these views I am disposed to insist very strongly on the importance of assigning to physics, that is to say to those subjects which we discuss in this section, a very prominent place in education. From the great sciences of observation, such as botany, or zoology, or geology, the young student learns to observe, or more simply, to use his eyes; he gets that education of the senses which is after all so important, and which a purely grammatical and literary education so wholly fails to give. From chemistry he learns, above all other things, the art of experimenting, and of experimenting for himself. But from physics, better as it seems to me than from any other part of science, he may learn to reason with consecutiveness and precision, from the data supplied by the immediate observation of natural phenomena. I hope we shall see the time when each successive portion of mathematical knowledge acquired by the pupil will be made immediately available for his instruction in physics; and when everything that he learns in the physical laboratory will be made the subject of mathematical reasoning and calculation. In some few schools I believe that this is already the case, and I think we may hope well for the future, both of mathematics and physics in this country, when the practice becomes universal. In one respect the time is favourable for such a revolution in the mode of teaching physical science. During the past few years a number of text-books have been made available to the learner, which far surpass anything that was at the

disposal of former generations of pupils, and which are probably as completely satisfactory as the present state of science will admit. It is pleasant to record that these text-books are the work of distinguished men who have always taken a prominent part in the proceedings of this section. We have Deschanel's Physics, edited, or rather re-written, by Prof. Everett, a book remarkable alike for the clearness of its explanations and for the beauty of the engravings with which it is illustrated; and passing to works intended for students somewhat further advanced, we have the treatises of Prof. Balfour Stewart on Heat, of Prof. Clerk Maxwell on the Theory of Heat, of Prof. Fleeming Jenkin on Electricity, and we expect a similar treatise on Light from another of our most distinguished members.

These works breathe the very spirit of the method which should guide both research and education in physics. They express the most profound and far-reaching generalisations of science in the simplest language, and yet with the utmost precision. With the most sparing use of mathematical technicalities, they are a perfect storehouse of mathematical ideas and mathematical reasonings. An old French geometer used to say that a mathematical theory was never to be considered complete till you had made it so clear that you could explain it to the first man you met in the street. This is of course a brilliant exaggeration, but it is no exaggeration to say that the eminent writers to whom I have referred have given something of this clearness and completeness to such abstract mathematical theories as those of the electrical potential, the action of capillary forces, and the definition of absolute temperature. A great object will have been attained when an education in physical science on the basis laid down in these treatises has become generally accepted in our schools.

I do not wish to close this address without adverting, though only for one moment, to a question which occupies the minds of many of the friends of science at the present time, the question what should be the functions of the State in supporting, or in organising, scientific inquiry. I do not mean to touch on any of the difficulties which attend this question, or to express any opinion as to the controversies to which it has given rise. But I do not think it can be out of place for the President of this section to call your attention to the inequality with which, as between different branches of science, the aid of Government is afforded. National observatories for astronomical purposes are maintained by this, as by every civilised country. Large sums of money are yearly expended, and most rightly expended, by the Government for the maintenance of museums, and collections of mineralogy, botany, and zoology; at a very recent period an extensive chemical laboratory with abundant appliances for research as well as for instruction has been opened at South Kensington. But for the physical sciences—such sciences as those of heat, light, and electricity—nothing has been done; and I confess I do not think that any new principle would be introduced, or any great burden incurred, capable of causing alarm to the most sensitive Chancellor of the Exchequer, if it should be determined to establish, at the national cost, institutions for the prosecution of these branches of knowledge, so vitally important to the progress of science as a whole. Perhaps also, upon this general ground of fairness, even the pure mathematicians might prefer a modest claim to be assisted in the calculation and printing of a certain number of Tables, of which even the physical applications of their science are beginning to feel the pressing need.

One word further on this subject of State assistance to Science, and I have done. It is no doubt true that for a great, perhaps an increasing, number of purposes, Science requires the assistance of the State, but is it not nearer to truth to say that the State requires the assistance of Science? It is my conviction that if the true relations between Science and the State are not recognised, it is the State, rather than Science, that will be the great loser. Without Science the State may build a ship that cannot swim, and may waste a million or two on experiments, the futile result of which Science could have foreseen. But without the State, Science has done very well in the past, and may do very well in time to come. I am not sure that we should know more of pure mathematics, or of heat, of light, or electricity than we do at this moment if we had had the best help of the State all the time. There are, however, certain things which the State might do and ought to do for Science. It, or corporations created by it, ought to undertake the responsibility of carrying on those great systems of observation which, having a secular character, cannot be completed within the life-time of a single generation, and cannot therefore be safely left to individual energy. One other thing the State ought to do for Science. It ought to pay scientific men properly for the services which they render directly to the State, instead of relying, as at present, on their love for their work as a means of obtaining their services on lower terms. If anyone doubts the justice of this remark, I would ask him to compare the salaries of the officers in the British Museum with those which are paid in other departments of the Civil Service.

But what the State cannot do for Science is to create the scientific spirit, or to control it. The spirit of scientific discovery is essentially voluntary; voluntary, and even mutinous, it will remain: it will refuse to be bound with red tape, or ridden by officials, whether well-meaning or perverse. You cannot have an Established Church in Science, and, if you had, I am afraid there are many scientific men who would turn scientific nonconformists.

I venture upon these remarks because I cannot help feeling that the great desire which is now manifesting itself on the part of some scientific men to obtain for Science the powerful aid of the State may perhaps lead some of us to forget that it is self-reliance and self-help which have made Science what it is, and that these are qualities the place of which no Government help can ever supply.

Report of the Committee appointed to consider the possibility of improving the methods of instruction in Elementary Geometry.

Until recently the instruction in elementary geometry given in this country was exclusively based upon Simson's modification of the text of Euclid. Of late years, however, attempts have been made to introduce other text-books agreeing with the ancient *Elements* in general plan, but differing from it in some important details of treatment. And in particular, the Association for the Improvement of Geometrical Teaching, having considered the whole question with great labour and deliberation, is engaged in the construction of a Syllabus, part of which is already completed. The Committee had thus to consider, *first*, the question of the plurality of text-books; *secondly*, certain general principles on which deviation from the ancient standard has been recommended; and, *thirdly*, the Syllabus of the Geometrical Association.

1. *On the Plurality of Text-Books.*

It has already been found that the practical difficulty of examination stands in the way of allowing to the geometrical teacher complete freedom in the methods of demonstration, and in the order of the propositions. The difficulty of demonstrating a proposition depends upon the number of assumptions which it is allowable to start from; and this depends upon the order in which the subject has been presented. When different text-books have been used, it thus becomes virtually impossible to set the same paper to all the candidates. And in this country at present teaching is guided so largely by the requirements of examinations, that this circumstance opposes a serious barrier to individual attempts at improvement. On the other hand, the Committee think that no single text-book which has yet been produced is fit to succeed Euclid in the position of authority; and it does not seem probable that a good book could be written by the joint action of selected individuals. It therefore seems advisable that the requisite uniformity, and no more, should be obtained by the publication of an authorised Syllabus, indicating the order of the propositions, and in some cases the general character of the demonstrations, but leaving the choice of the text-book perfectly free to the teacher. And the Committee believe that the authorisation of such a Syllabus might properly come from the British Association.

2. *On some Principles of Improvement.*

The Committee recommend that the teaching of Practical Geometry should precede that of Theoretical Geometry, in order that the mind of the learner may first be familiarised with the facts of the science, and afterwards led to see their connection. With this end the instruction in practical geometry should be directed as much to the verification of theorems as to the solution of problems.

It has been proposed to introduce what are called redundant axioms; that is to say, assumptions whose truth is apparently obvious, but which are not independent of one another. Such, for example, as the two assumptions that two straight lines cannot enclose a space, and that a straight line is the shortest

distance between any two of its points. It appears to the Committee that it is not advisable to introduce redundant axioms; but that all the assumptions made should be necessary for demonstration of the propositions, and independent of one another.

It appears that the Principle of Superposition might advantageously be employed with greater frequency in the demonstrations, and that an explicit recognition of it as an axiom of fundamental assumption should be made at the commencement,

The Committee think also that it would be advisable to introduce explicitly certain definitions and principles of general logic, in order that the processes of simple conversion may not be confounded with geometrical methods.

3. *The Syllabus of the Geometrical Association.*

The Association for the Improvement of Geometrical Teaching has issued (privately) a Syllabus covering the ground of the first four books of Euclid. The Committee are of opinion that the Syllabus is decidedly good, so far as it goes, but they do not wish to make a detailed report upon it in its present incomplete state. When it is finished, however, they will be prepared to report fully upon the merit of its several parts, to make such suggestions for revision as may appear necessary, and to discuss the advisability of giving to it the authority of the British Association. For this purpose the Committee request that they may be reappointed.

SECTION B.—CHEMISTRY

A report on *Essential Oils*, prepared by Dr. Wright and Dr. Gladstone, was read by the former.

On Black Deposits of Metals, by Dr. Gladstone, F.R.S.

If one metal be thrown down from solution by means of another metal, it does not always present itself of the same colour as it exhibits when in mass; in fact, most metals that are capable of being precipitated by substitution may be obtained in a black condition. The allied metals, platinum, palladium, and iridium, are generally if not always black when thus precipitated, and bismuth and antimony form black fringes and little else. Similar fringes are also formed by gold, but it also yields green, yellow, or lilac metal according to circumstances. Copper, when first precipitated on zinc, whether from a weak or a strong solution, is black; but in the latter case it becomes chocolate-coloured as it advances, or red if the action be more rapid. Lead, in like manner, is always deposited black in the first instance, though the growing crystals soon become of the well-known dull grey. Silver and thallium appear as little bushes of black metal on the decomposing plate, if the solution be very weak; otherwise they grow of their proper colour. Zinc and cadmium give a black coating, quickly passing into grey when their weak solutions are decomposed by magnesium. The general result may be stated thus: If a piece of metal be immersed in the solution of another metal which it can displace, the latter metal immediately makes its appearance at myriads of points in a condition that does not reflect light; but as the most favourably circumstanced crystals grow, they acquire the optical properties of the massive metal, the period at which the change takes place depending partly on the nature of the metal and partly on the rapidity of its growth. In the production of the black deposit of the copper-zinc couple lately employed by the author and Mr. Tribe to break up various compound bodies, there are several stages that may be noticed. At first an outgrowth of copper forms on the zinc; then, while this action is still proceeding, the couple itself acts upon the water or the sulphate of zinc in solution, the metallic zinc being oxidised, and hydrogen gas or black zinc being formed against the copper branches. This deposit of zinc was originally observed by Dr. Russell. The arrangement of the particles between the two metals in connection is supposed to be somewhat thus:—

$$Cu \mid Zn\,SO_4 \mid Zn\,SO_4 \mid H_2O \mid H_2O \mid Zn$$

which, by the conjoint power and chemical force, becomes—

$$Cu \mid Zn \mid Zn\,SO_4 \mid H_2\,SO_4 \mid H_2O \mid Zn$$

If there is still copper sulphate in the solution, this deposited zinc may in its turn become coated with copper, but if it remains exposed to water it is sure to become oxidised. The black deposit often assumes a brownish colour when this is the case. The copper on which zinc has been deposited gives a brassy streak when rubbed in a mortar; but the presence of oxide tends to prevent the sticking together of the detached pieces of metal, and thus the formation of a streak on pressure. If, however, the oxide be removed by acetic acid, the clean ramifications of metal, whether black or otherwise, conglomerate of their own accord in a remarkable way, and little pressure is required to obtain a yellowish metallic streak; while if hydrochloric acid be used, the zinc itself also dissolves with effervescence, and the conglomerating pieces of metal, when rubbed, give a coppery streak.

The Secretary read a paper communicated by Mr. Tribe, *On an Improved Specific Gravity Bottle.* The apparatus was originally designed for taking the specific gravity of inflammable liquids, but, as the President explained, it might be used for any other class of liquids.

Mr. W. H. Pike read a paper on *Several Homologues of Oxaluric Acid.*

The anhydrides of dibasic acids combine with urea and sulphourea to form bodies which have the general formula.

$$R\langle\begin{matrix}CO—NH—CO—NH_2\\COOH\end{matrix}$$

. The acids in this series which have been obtained are—

Succino-carbaminic acid, $\begin{matrix}CH_2—CO—NH—CONH_2\\|\\CH_2—COOH.\end{matrix}$

Succino-sulpho-carbaminic acid, $\begin{matrix}CH_2—CO—NH—CSNH_2\\|\\CH_2—COOH.\end{matrix}$

Citracon sulpho-carbaminic acid, $C_3H_4\langle\begin{matrix}CO.NH.CS.NH_2\\COOH.\end{matrix}$

Dr. Wright read a paper on *New Derivatives of Codeine and Morphine.*

It was a *résumé* of the results obtained in the previous year in continuation of those brought before the Association on former occasions. Morphine gave rise by treatment with sulphuric acid to polymerides precisely analogous to those obtained from codeine under similar conditions. Trimorphine and tetramorphine had been isolated, but di-morphine had not yet been formed. Derivatives from these bodies by the action of hydrochloric acid had been obtained and extended. By the action of hydrochloric acid on morphine a chlorinated product had been formed. By further treatment this formed apomorphine, a new body. Under the same circumstances codeine gave rise to a chlorinated base homologous with that from morphine. But further action gave rise not to the apomorphine, but to a somewhat similar body containing more of the elements of water. The action of zinc chlorides on morphine had also been examined; the final products were apomorphine and an isomeric base of the tetra series, intermediate substances being formed. The physiological properties of most of these new derivatives had been stated, and some connection made out in certain cases between the composition and the physiological action.

Friday, September 19

The report of the Committee for superintending the Monthly Reports of the Progress of Chemistry was read. The report bore testimony to the great good which the publication of the abstracts of chemical papers by the Chemical Society had already effected, and in the discussion which ensued it was stated that amongst the purposes to which the Association applied its funds, there was none which had proved more useful than this grant.

The report of the Committee on Siemens's Pyrometer was read by Prof. G. C. Foster, F.R.S.

The experiment of which the results were communicated to the Chemical Section of the Association in the Report presented last year, having shown that the exposure of the Pyrometer to a red heat caused an alteration of the Zero-point of the instrument, which was attributed by Prof. Williamson, in consequence of experiments on the behaviour of platinum heated in contact with silica in an atmosphere of carbonic oxide, to the chemical alteration of the platinum of the pyrometer-coil due to the joint action of the silica of the porcelain core on which the wire was wound, and of the reducing atmosphere existing inside the protecting iron tube. Mr. Siemens supplied the Committee with two pyrometers, in which, in order to guard against the cause of change above-mentioned, the platinum coil was incased in a platinum tube placed inside the outer iron tube. The ex-

periments of the Committee during the past year have been directed to testing the efficacy of this modification of the instrument. Owing to circumstances, these experiments have not been as numerous or complete as they were intended to be, but, as far as they go, they indicate that the addition of the platinum tube does not result in any perceptible improvement, since the two pyrometers supplied to the Committee were found to be as much changed, after being heated to a good red heat, as the instrument experimented upon last year.

Independent testimony, however, of considerable weight as to the value of Siemens's pyrometer, as an instrument for industrial use, has been borne by Prof. Adolf Weinhold, of Chemnitz (*Programm des königl. höherem Gewerbschule zu Chemnitz*, 1873), who after a careful, critical, and experimental review of various processes of pyrometry, arrives at the conclusion that this is the only ready-made pyrometer which can be recommended for use ("Von den fortig zu beziehenden Pyrometern ist nur das Siemens'sche brauchbar und empfehlenswerth," *loc. cit.* p. 42).

The Committee, therefore, consider that the further examination of Siemens's Pyrometer is a matter of sufficient importance to justify them in the recommendation that the Committee be re-appointed, and that the original grant of 30*l.*—no part of which has yet been expended—be renewed.

SECTION D.—Biology

DEPARTMENT OF ZOOLOGY AND BOTANY

Report of the Committee for the Foundation of Stations in different parts of the Globe.

The Committee reports that since the last meeting the Zoological Station at Naples has been completed, a photograph of which accompanies this report.

Both the mechanical and scientific arrangements inside require perhaps two more months to be finished, and though the cost of the whole has exceeded in no small degree the estimates, Dr. Dohrn hopes nevertheless to balance them by finding new means of income for the establishment. He has succeeded in obtaining a subvention of 1,500*l.* from the German Empire, and his scheme of letting working-tables in the laboratories of the station has met with general approval. Two tables have been let to Prussia and to Italy, one to Bavaria, Baden, and the Universities of Strasburg and Cambridge. A letter from the Dutch Minister of the Interior informs Dr. Dohrn that Holland accepts the offer of one table for the stipulated annual payment of 75*l.* Applications have also been made to the Imperial Government of Russia, both on the part of Dr. Dohrn and by different Russian scientific authorities. A correspondence has taken place between Dr. Dohrn and Professors Lovin and Steenstrup about a possible participation of the Scandinavian kingdoms, but has as yet led to no definite result. The case with respect to Switzerland and Saxony has been similar, but hopes are entertained that these countries may join the others in their endeavour to support the Zoological Station, and afford every facility to their naturalists of profiting by this new and powerful instrument of investigation.

Dr. Dohrn thinks it desirable to explain once more the leading ideas that have induced him to request the assistance of all these Governments and Universities.

The Zoological Station has sprung up altogether in consequence of the desire to facilitate investigation in marine zoology, and to enable naturalists to pursue their studies in the most effective manner and with the greatest possible economy of money and energy. All those zoologists that have visited Naples during the last year—amongst whom have been Professors Gegenbaur, Claus, Oscar Schmidt, Pagenstacher—consider that this end will be fully attained by the organisation and arrangements made or intended in the station. They all agreed that it is in the highest degree desirable that nobody who cares at all for the progress of zoology should fail to join Dr. Dohrn's exertions in bringing about a universal participation in the expense of keeping up the new establishment; and thus it is due to Prof. Oscar Schmidt's influence that the Imperial Government at Berlin hired a table for the University of Strasburg, and to the initiation of Prof. Pagenstacher that the Grand Ducby of Baden has also taken one table, whilst Prof. Claus has promised his services to induce the Austrian Government to take a similar step.

As is, we believe, universally known, no money-speculation whatever is contemplated by the founder of the Naples Station, in so far as money-speculation means a high interest and the return of the capital invested into the pocket of the founder. Nevertheless every honest means will be used to procure as large an income as possible, for more than one reason. There is not only the necessity incumbent upon the establishment to repay some of the capital to those who have lent money to Dr. Dohrn in order that he might complete the building in its actual enlarged state, a task for which his own means would not have sufficed, in spite of the German Government's subvention. There is further reserve funds to be provided for the eventuality that the income of the aquarium might at any time not cover the outlay for the year's management. And last, not least, it is just the plan to have every year a certain sum to spend for scientific pursuits. If, for instance, Prof. Dubois-Reymond, as he has expressed to Dr. Dohrn his wish to do so, should proceed to Naples to carry on experiments on the electric torpedo, it needs would require not inconsiderable means to buy the necessary apparatus and physiological instruments, and to provide the famous physiologist every day with fresh materials to conduct his investigations on a scale large enough to yield a distinct result. Or to enable embryologists to carry on an investigation on comparative selection-embryology, it requires means to buy large quantities of female sharks and skates, which are by no means so cheap as a foreigner might think. And for conducting well and accurately faunistic researches, everybody in this section knows what an amount of money must be spent in dredging-expeditions; how much trouble, how much time and work is necessary to get at the animals and to determine their identity or non-identity with the known and described species. And this is one of the foremost duties which the Zoological Station will propose to itself, as it is too well known how great a confusion exists with regard to systematic and faunistic questions of the Mediterranean fauna. To bring this confusion to an end it will require more than one lustrum and more than 1,000*l.* There may perhaps have risen a prejudice among systematists against the new establishment as one which, in consequence of the partiality of its leader for Darwinian views, might dispense altogether with Systematics. Nothing could be more erroneous than such an opinion. The leader of the zoological station is as little opposed to systematics as the Darwinian theory itself. He is of opinion—and the reporter can state this on the most absolute authority—that zoological battles may be best won according to Count Moltke's principle, "to march separately and to fight conjunctively," thus leaving to systematists their own route as well as to anatomists, physiologists, and embryologists, on condition only that they will, when meeting the enemy—error and ignorance—fight together. And he desires the zoological station to become such a battle-field, where all the different zoological armies may meet and fight their common adversaries.

That such wars need much of the one element, which, according to Monternouli, best secures victory—money, money, money, will be illustrated by two letters which Dr. Dohrn has received from Prof. Louis Agassiz, and which he has been authorised to publish.

The celebrated American naturalist writes, under the date "Museum of Comparative Zoology, Cambridge, Mass., June 10, 1873," the following:—

"It is a great pleasure and satisfaction to me, that I can tell you how, in consequence of the munificence of a wealthy New York merchant, it has become my duty to erect an establishment whose main object will be similar to that of your Naples station, only that teaching is to be united with it. The thing came thus to pass. During last winter I applied to our state authorities to secure more means for the museum in Cambridge (Mass.) Among the reasons, I alluded to the necessity of having greater means for trading purposes. I addressed my speech to our deputies, and it was afterwards reported in the newspapers. By chance the report fell into the hands of a rich and magnanimous tobacco-manufacturer, Mr. John Anderson, of New York. He sent, on the same day, a telegram asking me whether I would be at home on the following day for two friends, which I answered by 'yes.' The two gentlemen came, by order of Mr. Anderson, offering me a pretty little island in Buzzard Bay, for the purpose of erecting a zoological school. I accepted this offer, of course, but added, that without further pecuniary means it would be difficult to teach there. After two days, a sum of 50,000 dollars was handed over to me, and now I am erecting there a school for natural history, which at the same time will be a zoological station in the immediate neighbourhood of the gulf-stream, of the greatest assistance to our zoologists,

especially as splendid dredging ground. This certainly must greatly promote zoological study in the United States. Already forty teachers of our Normal and high schools have applied for this summer's lessons; besides, I will be accompanied thereto by my private students. Some of my special colleagues are ready to assist me, so that I may hope to obtain already some results before winter's approach."

The next letter is dated "Penikese, Aug. 13, 1873," and contains some more information :—

"The school has been opened on July 8. Some of my friends have assisted me as teachers, several other naturalists are occupied with special studies. The bottom of the sea is very rich, the general situation quite excellent. The solitude which prevails is a great help for our teaching purposes. As students, forty teachers of our public schools are present, besides ten younger gentlemen, who prepare for a scientific career.

"The buildings are very well constructed and adapted to their uses. The two chief houses have a length of 120 feet, and a breadth of 25 feet each. In the lower story are the laboratories each with 28 windows; every student occupies one window, and has for himself one aquarium. In the upper story of each house are 28 bed-rooms, for every student one. The professors and naturalists are lodged in another house of the shape of a Greek cross. The dining-room is in a third house, which contains also the kitchen and the servants' rooms. Besides we have an ice-house, a cellar for alcohol, stables for domestic animals; about one hundred sheep are feeding in the pasture grounds of the island; some smaller hutches contain rabbits, guinea-pigs, &c.

"Next year physical, chemical, and physiological, laboratories will be constructed. . . .

"I believe I did not tell you before, that my son presented me on my birthday with 100,000 dollars for the enlargement of the Museum. I intend to apply this sum chiefly to the augmentation of the collections, hoping the State will pay for the enlargement of the buildings. . . ."

These letters prove that the name of this committee has not been ill-chosen, for though the American Zoological Station has not been founded by its direct intervention, there can be little doubt that the foundation of the Zoological Station of Naples has been the signal for a new and powerful movement to assist zoological research.

Of course the American Station has met with such extraordinary advantages, that a competition between it and Naples Station as regards means and favourable circumstances would be all but hopeless for the latter. Nevertheless it may prove the most powerful instrument in carrying out strictly the self-supporting principle, by earning money through the Aquarium, and by letting tables in the laboratory. And though any act of munificence to the Naples Station is exceedingly desirable, and would be heartily welcomed (as the moment has not yet arrived, where any scientific establishment in this world had at its disposal more money than it knew how to spend) the greatest stress will always be laid upon these two elements.

The reporter is further glad to state that the library of the Zoological Station has recently been augmented. A magnificent gift has been made by the Zoological Society of London, which presented a complete set of its illustrated proceedings. The Royal Academies of Copenhagen, Naples, and Berlin, have also granted their biological publications, and promised to continue to do so in future. The Jenckenberg Institute in Frankfort-on-the-Main, as well as the Zoological Gardens of that city, have sent all their transactions; as has the Smithsonian Institution in Washington, with respect to its biological publications. Well-founded hopes are entertained that in a short time many other academies and scientific societies will follow the example of the above-mentioned.

German publishers have continued to send their biological publications gratis to the library of the station, and great quantities of books, pamphlets, and separata from publications in periodicals, have been forwarded from all parts of the scientific world through the kindness of the authors.

From the side of the Zoological Station, though still in an embryonic state, considerable activity has been displayed with regard to furnishing continental zoologists with collections of well-preserved marine animals. Thus Prof. Wilhelm Müller in Jena, has been supplied with Amphioxus and Tunicata, Prof. Greeff of Marburg with large quantities of Echinodermata; mixed collections of every kind of animals have been sent to Prof. Oscar Schmidt, Strasburg, Prof. Claus, Vienna, to the Jenckenberg Museum at Frankfort, the Natural History Society at Offenbach, and many others.

Several German zoologists have already announced their intention to come during next winter and work in the station; a similar announcement is made through an Italian zoologist and through Prof. Foster. I am informed that two young English biologists will arrive at the station in January.

The committee hopes this report will convince the section, that the year between the present and the last meeting of the British Association has been one of steady and considerable progress for the Zoological Station at Naples. The committee refrains from making any further proposition to the section, but expresses its wish, that every influence may be used to secure to the station at Naples such assistance, as will serve to promote the eminent scientific ends for which it has been erected.

DEPARTMENT OF ANATOMY AND PHYSIOLOGY

Opening Address by the President, Professor Rutherford

In addressing you upon the subjects of anatomy and physiology, I would invite your attention to some of the features which characterise these departments of biology at this present time, and to some recent advances in physiology, the consideration of which you will find to be possessed of deep interest and importance.

State of Anatomy

Anatomy, dealing as it does merely with the structure of living things, is a far simpler subject than physiology, whose province it is to ascertain and explain their actions. It was not a difficult thing to handle such instruments as a knife and forceps, and with their aid to ascertain the coarser structure of the body. Accordingly, the naked eye anatomy of man has been fully investigated, and although the same cannot be said of that of many of the lower animals, it is nevertheless, as far as this kind of inquiry is concerned, a mere question of time as regards its completion. But minute or microscopic anatomy is in a different position. Requiring, as it does, the microscope for its pursuit, it could not make satisfactory progress until this instrument had been brought to some degree of perfection. Doubtless much advantage is still to be derived from improvements in the construction of this instrument; but probably most of the future advances in our knowledge of the structure of the tissues and organs of the body may be expected to result from the application of new methods of preparing the tissues for examination with such microscopes as we now have at our disposal. This expectation naturally arises from what has been accomplished in this direction during the last fifteen years. For example, what valuable information has been gained regarding the structure of such soft tissues as the brain and spinal cord by hardening them with such an agent as chromic acid, in order that these tissues may be cut into thin slices for microscopical study. How greatly has the employment of such pigments as carmine and the aniline dyes facilitated the microscopical recognition of certain elements of the tissues. What a deal we have learned regarding the structure of the capillaries, and the origin of lymphatics, by the effect which nitrate of silver has of rendering distinctly visible the outlines of endothelial cells. What signal service chloride of gold has rendered in tracing the distribution of nerves by the property which it possesses of staining nerve fibrils, and thereby greatly facilitating their recognition amidst the textures. Moreover of what value osmic acid has been in enabling us to study the structure of the retina. In the hands of Lockhart Clarke, Beale, Recklinghausen, Cohnheim, Stultz, and others, these agents have furnished us with information of infinite value, and those who would advance microscopical anatomy may do so most rapidly by working in the directions indicated by these investigators. In human microscopical anatomy, indeed, there only remain for investigation things which are profoundly difficult, such as, for example, the structure of the brain, the peripheral terminations of nerves, the development of nerve tissue, and other subjects equally recondite But in the field of comparative anatomy there is far greater scope for the histological investigator. He has only to avail himself of those reagents and methods which have recently proved so useful in the microscopical anatomy of the vertebrates; he has only to apply those more fully than has yet been done to the invertebrates, and he will scarcely fail to make discoveries. For the lover of microscopical research, there is, moreover, a wide field of inquiry in the study of comparative embryology; that is to say

in the study of the development of the lower animals. Since it has become clear that a knowledge of the precise relations of living things one to another can only be arrived at by watching the changes through which they pass in the course of their development, research has been vigorously turned in this direction, and although an immense mass of facts has long since been accumulated regarding this question, Parker's brilliant researches on the development of the skull give an indication of the great things we may yet anticipate from this kind of research. Speaking of microscopical study before this audience, I cannot but remember that in this country more than in any other we have a number of learned gentlemen who, as amateurs eagerly pursue investigations in this department. I confess that I am always sorry to witness the enthusiastic perseverance with which they apply themselves to the prolonged study of markings upon diatoms, seeing that they might direct their efforts to subjects which would repay them for their labours far more gratefully. I would venture to suggest to such workers that it is now more than ever necessary to abandon all aims at haphazard discoveries, and to approach microscopy by the only legitimate method, of undergoing a thorough preliminary training in the various methods of microscopical investigation by competent teachers, of whom there are now plenty throughout the country.

State of Physiology

With regard to physiology, the present standpoint is not so high as in the case of anatomy. Physiology, resting as it does upon a tripod consisting of anatomy, physics or mechanics, and chemistry, is many-sided. The most minute anatomy, the most recondite physics, and the most complex chemistry, have all to be taken into account in the study of the physiology of living things; so that it is not surprising that it should, in its development, lag behind the comparatively elementary subject—anatomy. Until not so very long ago anatomy and physiology were in most of our medical schools taught by the same professor, who, although professing to teach both subjects, was generally more an anatomist than a physiologist. This arrangement gave to physiology a bias which was eminently anatomical, and this bias continued in many quarters, notwithstanding the separation of the physiological from the anatomical tuition. I am aware that there are still some distinguished anatomists who intermingle physiological with anatomical teaching. I am not questioning the usefulness of the practice when carried to a moderate extent. I wish merely to point out what appears to me to have been a result of the practice, and I believe that the result was to give to physiology an anatomical tendency. It was natural for the anatomist who dealt with visible structure to constantly refer to this in explaining physiological action or function. The physiologist with the anatomical tendency always tried to explain a difference in the action or function of a part by a difference in its evident structure, and when his microscope failed to show any structural difference between the cells which form saliva and those which produce pancreatic fluid, between the egg of a rabbit and that of a dog, he, baffled on the side of anatomy, was too ready to adopt the conclusion that inasmuch as the microscope reveals no difference in the structure there is really no structural difference between them, and that the only way in which the difference in action can be explained is by having recourse to the old hypothesis that the metamorphoses of matter, and the actions of force are in the living world regulated by a metaphysical entity termed a vital principle, and that dissimilar actions by similarly constructed parts are only to be explained by referring them to the operations of this principle. After alluding further to the hypothesis of the vital principle and its supposed actions, and after stating that he did not follow the teaching of those who still adhere to this doctrine, the lecturer said that, viewed from the physical side, there appears to be no reason for supposing that two particles of protoplasm, which possess a similar microscopic structure, must act in the same way; for the physicist knows that molecular structure and action are beyond the ken of the microscopist, and that within apparently homogeneous jelly-like particles of protoplasm there may be differences of molecular constitution and arrangement which determine widely different properties.

A great change is now taking place in physiological tuition in this country—a superabundance of physiological anatomy, and an almost entire absence of experiment, are no longer the characteristic features of our tuition. The study of physics, too much neglected, is happily now being more and more regarded as important in the preliminary training of the physiologist, as the study of anatomy and of chemistry; and I trust that the day is not far distant when in our medical schools the thorough education of our students in mathematics and physics will be insisted upon as absolutely essential elements in their preliminary education. Until this is done physiology will not advance in this country so rapidly as we could wish. I would not in this place have alluded to a question concerning medical education, but for the fact that the progress of physiology will always greatly depend upon the education of medical men, for only those who are conversant with physics and chemistry, and who, in addition, are acquainted with the phenomena of disease—that is to say, with abnormal physiological conditions—can handle physiology in all its branches. Physiology owes not a little to a study of pathology—that is, of abnormal physiological states. The study of a diseased condition has, on several occasions, given a clue to the discovery of the function of an organ. Nothing was known regarding the function of the spleen until the pathologist observed that an increase in the number of white corpuscles in the blood is commonly associated with an enlargement of this organ. Hence arose the now accepted doctrine that the spleen is concerned in the growth of blood corpuscles. The key to our knowledge of the functions of certain parts of the brain has also been supplied by a study of the diseased conditions of that organ. The very singular fact that the right side of the body is governed by the left, and not by the right side of the brain, was ascertained by observing that palsy of the right side of the body is associated with certain diseased conditions of the left side of the brain. That the corpus striatum is concerned in motion, while the optic thalamus is concerned in sensation; that intellectual operations are manifested specially through the cerebral hemispheres, are conclusions which were indicated by the study of diseased conditions. Moreover, by the pursuit of the same line of inquiry the key has been given to the discovery of many other facts regarding the brain functions. Some years ago M. Broca made the remarkable observation that, when a certain portion in the front part of the left side of the brain becomes disorganised by disease, the person loses the power of expressing his thoughts by words, either spoken or written. He can comprehend what is said to him, his organs of articulate speech are not paralysed, and he retains his power of writing, for he can copy words when told to do so, but when he is asked to give expression to his thoughts by speaking or by writing, or even to tell his name, he is helpless. With a palsy of a portion of his brain, he has lost his power of finding words—he has lost his memory for words; and mark you, although he loses his power of finding words, his intelligent perception of what passes around him and of what is said to him is not lost. It is true that this condition of aphasia, as it is termed, has been found to exist when various parts of the brain have been diseased; for example, it has been found to coexist with a diseased state of the posterior instead of the anterior part of the cerebrum. This fact renders it very difficult as yet to assign a precise locality to the faculty of speech. It is not, however, my intention to discuss this question, for my object is merely to show how the study of disease has given a clue to the physiologist. Broca's observation led to the thought that, after all, the dreams of the phrenologists would be realised, in so far as they supposed that the various mental operations are made manifest through certain definite territories of the brain.

It has until lately been supposed that the convolutions of the cerebrum are entirely concerned in purely intellectual operations, but this idea is now at an end. It is now evident, from recent researches, that in the cerebral convolutions—that is, in the part of the brain which was believed to minister to intellectual manifestations—there are nerve-centres for the production of voluntary muscular movements in various parts of the body. It has always been taught that the convolutions of the brain, unlike nerves in general, cannot be stimulated by means of electricity. This, although true as regards the brains of pigeons, fowls, and perhaps other birds, has been shown by Fritsch and Hitzig to be untrue as regards mammals. These observers removed the upper portion of the skull in the dog, and stimulated small portions of the exposed surface of the cerebrum by means of weak galvanic currents, and they found that when they stimulated certain definite portions of the surface of the convolutions in the anterior part of the cerebrum, movements are produced in certain definite groups of muscles on the opposite side of the body. By this new method of exploring the functions of the convolutions of the brain, these investigators showed that in certain cerebral convolutions, there are centres for the nerves presiding over the muscles

of the neck, the extensor and adductor muscles of the forearm, for the flexor and rotator muscles of the arm, the muscles of the foot, and those of the face. They, moreover, removed the portion of the convolution on the left side of the cerebrum, which they had ascertained to be the centre for the movements of the right forelimb, and they found that after the injury thus inflicted, the animal had only an imperfect control over the movements of the part of the limb in question. Recently, Dr. Hughlings Jackson, from the observation of various diseased conditions in which peculiar movements occur in distinct groups of muscles, has adduced evidence in support of the conclusion that in the cerebral convolutions are localised the centres for the production of various muscular movements. Within the last few months these observations have been greatly extended by the elaborate experiments of my able colleague in King's College, Prof. Ferrier.

Adopting the method of Fritsch and Hitzig—but instead of using galvanic he has employed Faradic electricity, with which, strange to say, the investigators just mentioned obtained no very definite results—he has explored the brain in the fish, frog, dog, cat, rabbit, and guinea-pig, and lately in the monkey. The results of this investigation are of great importance. He has explored the convolutions of the cerebrum far more fully than the German experimenters, and has investigated the cerebellum, corpora quadrigemina, and several other portions of the brain not touched upon by them. There is, perhaps, no part of the brain whose function has been more obscure than the cerebellum. Dr. Ferrier has discovered that this ganglion is a great centre for the movements of the muscles of the eyeballs. He has also very carefully mapped out in the dog, cat, &c., the various centres in the convolutions of the cerebrum, which are concerned in the production of movements in the muscles of the eyelids, face, mouth, tongue, ear, neck, fore and hind feet, and tail. He confirms the doctrine that the corpus striatum is concerned in motion, while the optic thalamus is probably concerned in sensation, as are also the hippocampus major and its neighbouring convolutions. He has also found that in the case of the higher brain of the monkey there is what is not found in the dog or cat—to wit, a portion in the front part of the brain, whose stimulation produces no muscular movement. What may be the function of this part, whether or not it specially ministers to intellectual operations, remains to be seen. These researches of Fritsch, Hitzig, Jackson, and Ferrier, mark the commencement ot a new era in our knowledge of brain function. Of all the studies in comparative physiology there will be none more interesting, and few so important, as those in which the various centres will be mapped out in the brains throughout the vertebrate series. A new, but this time a true, system of phrenology will be founded upon them; by this, however, I do not mean that it will be possible to tell a man's faculties by the configuration of his skull, but that the various mental faculties will be assigned to definite territories of the brain, as Gall and Spurzheim long ago maintained, although their geography of the brain was erroneous.

I have alluded to this subject, not only because it affords an illustration of the service which a study of diseased conditions has rendered to physiology, but also because these investigations constitute the most important work which has been accomplished in physiology for a very considerable time past.

Revival of Physiology in England

We may, I think, term this the renaissance period of English physiology. It seems strange that the country of Harvey, John Hunter, Charles Bell, Marshall Hall, and John Reid, should not always have been in the front rank as regards physiology. The neglect of physics must be admitted as a cause of this; it is also to be attributed to the, until a few years ago, almost entire absence of experimental teaching; but it would be unjust not to attribute it in great measure to the limited appliances possessed by our physiologists. It is to be remembered that physiology could not be successfully cultivated without proper laboratories, with a supply of expensive apparatus. Without endowments from public or private resources, how can such institutions be properly fitted up and maintained by men who can, for the most part, only turn to physiological research in moments snatched from the busy toil of a profession so laborious as that of medicine. In defiance of these difficulties we are now striving to hold our place in the physiological world. A new system of physiological tuition is rapidly extending over the country. In the London schools, in Edinburgh, Cambridge, Manchester, and elsewhere, earnest efforts are being made to give a thoroughly practical aspect to the tuition of our science, and notwithstanding the imperfect results which must necessarily ensue in the absence of suitable endowment, we can nevertheless point to the fact that the effect of these efforts has been to awaken a love for physiological research in the mind of many a student, and the results of this awakening are already apparent in the archives of Royal Societies, in the "Journal of Anatomy and Physiology," and elsewhere. But physiological research is most expensive and laborious, and it is, moreover, unremunerative. The labours of the physiologist are entirely philanthropic; all his researches do nothing but contribute to the increase of human happiness by the prevention of disease, and the amelioration of suffering; and I would venture to suggest to those who are possessed of wealth and of a desire to apply it for the benefit of society, that in view of the wholly unselfish and philanthropic character of physiological labours, they could not do better than follow the admirable example set by Miss Brackenbury in endowing a physiological laboratory in connection with Owens College, in Manchester. The endowment of a dozen such laboratories throughout the country would immensely aid in the development of physiological research amongst us.

We anticipate great benefit to the community not only from an advance of physiology, but from a diffusion of a knowledge of its leading facts amongst the people. This is now being carried out in our schools on a scale which is annually increasing. Thanks to the efforts of Huxley, the principles of physiology are now presented in a singularly palatable form to the minds of the young. The instruction communicated does not consist of technical terms and numbers, but in the elucidation of the principal events which happen within our bodies, together with an explanation of the treatment which they must receive in order to be maintained in health. Considering how much may be accomplished by these bodies of ours if they be properly attended to and rightly used, it seems to be a most desirable thing that the possessor of the body should know something about its mechanism, not only because such knowledge affords him much material for suggestive thought—not only because it is excellent mental training to endeavour to understand the why and the wherefore of the bodily actions, but also because he may greatly profit from a knowledge of the conditions of health. A thorough adoption of hygienic measures—in other words, of measures which are necessary to preserve individuals in the highest state of health—cannot be hoped for until a knowledge of fundamental physiological principles finds its way into every family. This country has taken the lead in the attempt to diffuse a sound knowledge of physiological facts and principles among the people, and we may fairly anticipate that this will contribute not a little to enable her to maintain her high rank amongst nations; for every step which is calculated to improve the physiological state of the individual must inevitably contribute to make the nation successful in the general struggle for existence.

DEPARTMENT OF ANTHROPOLOGY

Opening Address by the President, John Beddoe, F.R.S.

The position of Anthropology in the British Association, as a permanent department of the Section of Biology, being now fully assured, and its relations to the allied and contributory sciences beginning to be well understood and acknowledged, I have not thought it necessary, in opening the business of the department, to follow the examples of my predecessors, Prof. Turner and Colonel Lane Fox. The former of these gentlemen, at our Edinburgh Meeting, devoted his opening address to the definition, history, and boundaries of our science; the latter, at Brighton, in the elaborate essay which many of you must have listened to, not only discussed its relations to other sciences, but gave an illustrative survey of a great portion of its field and of several of its problems.

But while, on the one hand, I feel myself incompetent to follow these precedents with success, on the other hand I am encouraged to take a different line by the consideration that if, as we are fond of saying in this department, "the proper study of mankind is man"—if, that is, anthropology ought to interest everybody, then assuredly the anthropology of Yorkshire ought to interest a Yorkshire audience.

Large as the county is, and sharply marked off into districts by striking diversities of geological structure, of climate and of surface, there is an approach to unity in its political and ethnological history which could scarcely have been looked for.

Nevertheless we must bear in mind the threefold division of the shire—not that into ridings, but that pointed out by nature. We have, first, the western third, the region of carboniferous limestone and millstone-grit, of narrow valleys and cold rainy moorlands; secondly, the great plain of York, the region, roughly speaking, of the Trias, monotonously fertile, and having no natural defence except its numerous rivers, which indeed have sometimes served rather as a gateway to the invader than as a bulwark against him; to this plain Holderness and the Vale of Pickering may be regarded as eastern adjuncts. Thirdly, we have the elevated region of the east, in the two very dissimilar divisions of the moorlands and the wolds; these are the most important parts of Yorkshire to the prehistoric archæologist; but to the modern ethnologist they are comparatively of little interest.

The relics of the palæolithic period, so abundant in the south of England, are, I believe, almost wholly wanting in Yorkshire, where archæology begins with the neolithic age, and owes its foundations to Canon Greenwell of Durham, Mr. Mortimer of Driffield, Mr. Atkinson of Danby, and their predecessors in the exploration of the barrows of Cleveland and the Wolds, whose results figure largely in the "Crania Britannica" of Davis and Thurnam,—themselves, by the way, both natives of the city of York.

The earliest inhabitants we can distinctly recognise were the builders of certain long barrows, such as that of Scamridge in Cleveland. There is still, I believe, some difference of opinion among the anthropologists of East Yorkshire (where, by the way, in the town of Hull, the science flourishes under the auspices of a local Anthropological Society)—still, I say, some difference of opinion as to whether the long-barrow folk were racially diverse from those who succeeded them and who buried their dead in round barrows. But Canon Greenwell at least adheres to Thurnam's doctrine, and holds that Yorkshire, or part of it, was occupied at the period in question, perhaps 3,000 years ago, by a people of moderate or rather short stature, with remarkably long and narrow heads, who were ignorant of metallurgy, who buried their dead under long ovoid barrows, with sanguinary rites, and who labour under strongly-founded suspicions of cannibalism.

Of the subsequent period, generally known as the bronze age, the remains in Yorkshire, as elsewhere, are vastly more plentiful. The Wolds especially, and the Cleveland hills, abound with round barrows, in which either burnt or unburnt bodies have been interred, accompanied sometimes with weapons or ornaments of bronze, and still more often with flint arrowheads. Where bones are found, the skull presents what Barnard Davis considers the typical British form; *i.e.* it is generally rather short and broad, of considerable capacity and development, with features harsh and bony. The bodily frame is usually tall and stalwart, the stature often exceeding 6 ft., as in the well-known instance of the noble savage of Gristhorpe, whose skeleton is preserved in the Scarborough Museum.

Though certain facts, such as the known use of iron in Britain before Cæsar's time, and its extreme rarity in these barrows, and some little difference in proportion between the skulls just described and the type most common among our modern British Kelts, do certainly leave room for doubt, I have little hesitation in referring these round barrows to the Brigantes and Parisii,* the known occupants of Yorkshire before the Roman conquest.

Both what I will term provisionally the pure long-barrow and the pure round-barrow types of cranium are represented among our modern countrymen. But the former is extremely rare, while the latter is not uncommon. It is probable enough that the older type may, in amalgamating with the newer and more powerful one, have bequeathed to the Kelts of our own time the rather elongated form which prevails among them. Whether this same older type was really Iberian is a point of great interest, not yet ripe for determination.

Another moot point is the extent to which the population of modern England is derived from the colonists introduced under the Roman occupation. It is my own impression that the extent, or rather the intensity of such colonisation has been over-estimated by my friend Mr. Thomas Wright and his disciples. I take it that, in this respect, the Roman occupation of Britain was somewhere between our own occupations of India and of South Africa, or perhaps still more nearly like that of Algeria by the French, who have their roads, villas, and military establishments, and even considerable communities in some of the towns, but who constitute but a very small percentage of the population, and whose traces would almost disappear in a few generations, could the communication with the mother-country be cut off.

If, however, any traces of the blood of the lordly Romans themselves, or of that more numerous and heterogeneous mass of people whom they introduced as legionaries, auxillaries, or colonists, are yet recognisable anywhere in this county, it may probably be in the city of York, or in the neighbourhood of Catterick. The size and splendour of ancient Eburacum, its occupation at various times as a sort of military capital by the Emperor Severus and others, its continued existence through the Anglian and Anglo-Danish periods, and its subsequent comparative freedom from such great calamities * or vicissitudes as are apt to cause great and sudden changes of population, might almost induce us to expect to find such vestiges. If Greek and Gothic blood still assert themselves in the features and figures of the people of Arles, if Spanish characteristics are still recognisable in Bruges, why not Italian ones in York? It may be so; but I must confess that I have not seen them, or have failed to recognise them. Catterick, the site of ancient Cataractonium, I have not visited.

Of the Anglian conquest of Yorkshire we know very little, except that it was accomplished gradually by successive efforts, that the little district of Elmet, in the neighbourhood of Leeds, continued British for a while, and that Carnoban, which is almost certainly Craven, is spoken of by a Welsh writer as British after all the rest of the country had ceased to be so—a statement probable enough in itself, and apparently corroborated by the survival of a larger number of Keltic words in the dialect of Craven than in the speech of other parts of Yorkshire.

Certain regulations and expressions in the Northumbrian laws, among others the less value of a churl's life as compared with that of a thane, have been thought to indicate that the proportion of the British population that remained attached to the soil, under Anglian lords, was larger in the north than in some other parts of England. The premisses are, however, insufficient to support the conclusion; and, on the other hand, we are told positively by Bede that Ethelfrith Fleisawr drove out the British inhabitants of extensive districts. The singular discoveries of Boyd Dawkins and his coadjutors in the Settle Cave, where elaborate ornaments and enamels of Romano-British type are found in conjunction with indications of a squalid and miserable mode of life long endured, attest clearly the calamities of the natives about that period (the early part of the seventh century), and show that even the remote dales of Craven, the least Anglian part of Yorkshire, afforded no secure refuge to the Britons of the plains, the unfortunate heirs of Roman civilisation and Roman weakness. The evidence yielded by local names does not differ much from that of the same kind in other parts of England. It proves that enow of Welshmen survived to transmit their names of the principal natural features (as Ouse, Derwent, Wharfe, Dun, Roseberry, Pen-y-gent), and of certain towns and villages (as York, Catterick, Beverley, and Ilkley), but not enow to hinder the speedy adoption of the new language, the re-naming of many settlements, and the formation of more new ones with Anglian names. The subsequent Danish invasion slightly complicated this matter; but I think it is safe to say that the changes in Yorkshire were more nearly universal than in counties like Devonshire, where we know that the descendants of the Welsh constitute the majority. If the names of the rivers Swale and Hull be really Teutonic, as Greta undoubtedly is, the fact is significant; for no stream of equal magnitude with the Swale, in the south of England, has lost its Keltic appellation.

We do not know much of the Anglian type, as distinguished from the Scandinavian one which ultimately overlaid it almost everywhere to a greater or less depth. The cranial form, if one may judge of it by the skulls found in the ancient cemetery of Lamel-Hill near York, was not remarkably fine, certainly not superior to the ancient British type as known to us, to which, moreover, it was rather inferior in capacity. There is some resemblance between these Lamel-Hill crania and the Belair or Burgundian type of Switzerland, while the Sion or Helvetian type of that country bears some likeness to our own Keltic form.

* It has been conjectured that the Parisii were Frisians; but I think it very unlikely.

* Unless indeed York was the "municipal town" occupied by Cadwalla and besieged by his Anglian adversaries.

The group of tumuli called the Danes' Graves, lying near Driffield, and described by Canon Greenwell in the *Archæological Journal*, have yielded contents which are a puzzle for anthropologists. Their date is subsequent to the introduction of the use of iron. Their tenants were evidently not Christians; but they belonged to a settled population. The mode of interment resembles nothing Scandinavian; and the form of the crania is narrower than is usual, at least in modern times, in Norway and Denmark. It is hazardous to conjecture anything about them; but I should be more disposed to refer them to an early Anglian or Frisian settlement than to a Danish one.

We come now to the Danish invasions and conquest, which, as well as the Norman one that followed, was of more ethnological importance in Yorkshire than in most other parts of England. The political history of Deira, from the ninth century to the eleventh, the great number of Scandinavian local names (not greater, however, in Yorkshire than in Lincolnshire), and the peculiarities of the local dialect, indicate that Danes and Norwegians arrived and settled, from time to time, in considerable numbers. But in estimating these numbers we must make allowance for their energy and audacity, as well as for the very near kinship between the Danes and the Northumbrian Angles, which, though it did not prevent sanguinary struggles between them at first and great destruction of life, must have made amalgamation easy, and led the natives readily to adopt some of the characteristics of the invaders.

Whatever the Danish element in Yorkshire was, it was common to Lincolnshire and Nottinghamshire, and to the north-eastern part of Norfolk; and it was comparatively weak in Northumberland and even in Durham. In Yorkshire itself, it was irregularly distributed, the local names in *by*, *toft*, and *thwaite*, and the like being scattered in a more or less patchy manner, as may be seen on Mr. Taylor's map. They are very prevalent in Cleveland, as has been shown by Mr. Atkinson. Again, the long list of the landowners of the county under Edward the Confessor, given in Domesday Book, contains a mixture of Anglian with Scandinavian names, the latter not everywhere preponderating. Here, again, Cleveland comes out very Danish. I am inclined to believe that the Anglian population was, in the first fury of the invasion, to some extent pushed westwards into the hill-country of the West Riding, though even here distinctly Danish names, such as Sowerby, are quite common. Beverley and Holderness perhaps remained mainly Anglian.

The Norman conquest fell upon Yorkshire, and parts of Lancashire and Durham, with unexampled severity. It would seem that the statement of William of Malmesbury that the land lay waste for many years through the length of sixty miles, was hardly, if at all exaggerated. The thoroughness and the fatal effects of this frightful devastation were due, no doubt, partly to the character of William, who, having once conceived the design, carrried it out with as much completeness and regularity as ferocity, and partly to the nature of the country, the most populous portion of which was level and devoid of natural fastnesses or refuge, but also, in some degree, to the fact that the Northumbrians had arrived at a stage of material civilisation at which such a mode of warfare would be much more formidable than while they were in a more barbarous condition, always prepared for fire and sword, and living, as it were, from hand to mouth. Long ages afterwards the Scots told Froissart's informants that they could afford to despise the incursions of the English, who could do them little harm beyond burning their houses, which they could soon build up again with sticks and turf; but the unhappy Northumbrians were already beyond that stage.

In all Yorkshire, including parts of Lancashire, Westmoreland, and Cumberland, Domesday numbers only about 500 freemen, and not 10,000 men altogether. This great destruction, or rather loss of population (for it was due in some measure to the free or forced emigration to Scotland of the vanquished), did not necessarily imply ethnological change. Let us examine the evidence of Domesday on this point. It agrees with that of William of Malmesbury, that the void created by devastation remained a void, either entirely or to a great extent. Whole parishes and districts are returned as "waste." In one instance 116 freemen (sockmanni) are recorded to have held land in King Edward's time, of whom not one remained; in another, of 108 sokemen only 7 remained. But foreigners *did* settle in the county to some extent, either as military retainers of the new Norman lords, as their tenants, or as burgesses in the city of York, where 145 francigenæ (Frenchmen) are recorded as inhabiting houses.

Of the number maintained by way of garrisons by the new nobility, one can form no estimate; but considering the impoverished and helpless condition of the surviving natives, such garrisons would probably not be large. But from the enumeration of mesne tenants, or middlemen, some inferences may perhaps be drawn. On six great estates, comprising the larger part of Eastern and Central Yorkshire, sixty-eight of these tenants are mentioned by name, besides 11 milites, or men-at-arms. Only 11 of the 68 bear names undoubtedly English; and none of them have large holdings, as is the case with some of those bearing Norman names. On the lands of Drogo de Bevrere, about Holderness, several of the new settlers were apparently Flemings.

The western part of the county, however, or the greater part of it, had been granted to two lords who pursued a more generous policy. Alan, count of Bretagne, the founder of Richmond, had twenty-three tenants, besides twelve milites, men-at-arms with very small holdings. Of the twenty-three, nine were Englishmen, in several instances holding as dependents the whole or part of what had been their own freeholds. The Breton ballads and traditions seem to favour the supposition that Count Alan's Breton followers mostly returned home; and Count Hersart de la Villemarquée, the well-known Breton archæologist, informed me that his ancestors returned to Bretagne from Yorkshire in the twelfth century. On the whole, I do not think it probable that the Breton colony was numerous enough to leave distinct and permanent vestiges; but if any such there are, they may be looked for in the modern inhabitants of Richmond and Gilling.

Ilbert de Lacy, again, had a great domain, including most part of the wapentakes of Morley, Agbrigg, Skyrack, and Staincross, extending, that is, far to the north and south of our present place of meeting. Bradford, by the way, was then hardly so important and wealthy as at the present day. A thane named Gamel had held it at the time of Edward the Confessor, when it was valued at 4*l*. yearly; but at the time of the survey it was waste, and worth nothing.

Sixty-seven mesne tenants under Ilbert de Lacy are mentioned, of whom no less than forty-one bore English names, and only twenty-six foreign ones. It is probable, therefore, that in this important part of the county the ethnological change wrought by the Conquest was not greater, if so great as in England generally, but that in the centre, east, and north-east it was of some moment, and that the Scandinavian element of population suffered and lost more than the Anglian.

It might be a matter of some interest to a minute ethnologist or antiquarian to trace out fully the local history after the Conquest from an ethnological point of view, investigating particularly the manner and source of the repeopling of the great plain of York.

After this had been completed, no further change of ethnological importance took place during several centuries. The Flemings and Frisians, who, in considerable numbers, settled at various times in Leeds, Halifax, and Wakefield, whether drawn hither by the course and opportunities of trade, or driven by the persecutions of Philip II. and the Roman Catholics, brought in no new element, and readily amalgamated with the kindred race they found here.

The more recent immigrations into the West Riding and Cleveland from all parts of Britain, and even from the Continent, have interest of other kinds. Vast as they have been, they have not yet obscured in any great degree the local types, physical or moral, which still predominate almost everywhere, though tending of course to assimilate themselves to those of the mixed population of England in general.

In describing these types I prefer to use the words of Prof. Phillips, who, in his "Rivers of Yorkshire," has drawn them in true and vivid colours. He speaks of three natural groups :—

"First. Tall, large-boned, muscular persons; visage long, angular; complexion fair or florid; eyes blue or grey; hair light, brown or reddish. Such persons in all parts of the county form a considerable part of the population. In the North Riding, from the eastern coast to the western mountains, they are plentiful.

Second. Person robust; visage oval, full and rounded; nose often slightly aquiline; complexion somewhat embrowned, florid; eyes brown or grey; hair brown or reddish. In the West Riding, especially in the elevated districts, very powerful men have these characters.

"Third. Person of lower stature and smaller proportions; visage short, rounded, complexion embrowned; eyes very dark,

elongated; hair very dark. Individuals having these characters occur in the lower grounds of Yorkshire, as in the valley of the Aire below Leeds, in the vale of the Derwent, and the level regions south of York."

I have chosen to quote from Professor Phillips rather than to give descriptions of my own, both because his acquaintance with the facts is more extensive than mine, and because I desire to pay my small tribute to the genius and insight of the author of a work so unique and so admirable as his upon Yorkshire.

He ascribes the first and second of these types mainly to a Scandinavian, the last to a Romano-British, or possible Iberian origin; and appears to think that the first, the tall, fair, long-faced breed, resembles the Swedes, and that the second, the brown burly breed of the West Riding, is more Norwegian in character. He probably selects the Swedes as the purest or most typical of the Scandinavian nations. For my own part, I am disposed to treat the first as Norwegian more than Anglian, the second as Anglian rather than Norse, and Norse rather than British. The tall fair type engrosses most of the beauty of the north, having often an oval face, with a fine straight profile nearly approaching the Greek, as Knox and Barnard Davis, two close observers, have both remarked. And it is markworthy that it reappears in force almost everywhere in Britain where Norse blood abounds, *e.g.* in Shetland, Orkney, Caithness, in the upper class of the Hebrideans, in Cumberland, Westmoreland, and Lonsdale, about Lincoln (where Professor Phillips also noted it) and the Vale of Trent, and about the towns of Waterford and Wexford. The second type, on the other hand, much resembles a prevailing form in Staffordshire, a very Anglian county. A notable point about it is the frequency of eyes of a neutral, undecided tint, between light and dark, green, brown, and grey, the hair being comparatively light. The third is of more doubtful and of more manifold origin. Iberian, Britokeltic, Roman, Breton, Frenchman, may all, or any of them, have contributed to its prevalence. I am inclined to think, though on rather slender grounds, that it is common in some of the districts depopulated by the Conqueror. Professor Phillips speaks of its smaller proportions, but it includes many robust men. It is probably far from well representing the Brigantian type, which seems to me to have influenced the other types, but rarely to crop out all purely.

The breadth of the head is, on the average, somewhat greater in Yorkshire than in other parts of Britain; so we are informed by the hatters. In this the natives of Yorkshire agree with those of Denmark and Norway, who have rather broader heads than those of Sweden and of Friesland.

I have already spoken of the colours of the eyes and hair. The latter is, on the whole, lighter in Yorkshire than in most parts of England; but dull rather than bright shades prevail. In the east, at Whitby, Bridlington, and Beverley, in Teesdale and Middle Airedale, light hair is particularly abundant; in Craven, as might have been expected, it is less so. Other parts of the county are not so well known to me, and in this matter I have to trust to my own observations.

As to the stature and bulk of the people, however, I have much and accurate information, through the kindness of numerous observers, some of them of repute as naturalists. These are Mr. Atkinson of Danby, Mr. Tudor of Kirkdale, Dr. Wright of Melton, Dr. Christy of the North Riding Asylum, Drs. Kelburne King and Casson of Hull, Mr. Ellerton of Middlesborough, Mr. Wood of Richmond, Mr. Kaye of Bentham, Mr. Edy of Grassington, Dr. Paley of Ripon, Dr. Ingham of Haworth, Messrs. Armitage of Farnley, Dr. Wood of Kirkby Overblow, Dr. Aveling and Mr. Short of Sheffield, Mr. Miller, late of Wakefield Prison, and a clergyman on the Wolds, whom the prejudices or fears of his parishioners will not allow me to name. "A Yorkshireman," complained this last gentleman, "is a difficult animal to catch and weigh and measure;" but a very large number of them have been subjected to these processes by my obliging correspondents. The general result is that in the rural districts they are remarkably tall and stalwart, though not, except in parts of the west, so heavy as their apparent size would indicate—but that in the towns, and especially in Sheffield, they are rapidly degenerating; and I conclude from the Haworth report that the same is the case in the manufacturing villages. In many of the rural districts the average ranges between 5 ft. 8 in. and 5 ft. 9 in., and about Richmond and on the Bentham Fells is considerably higher: while at Sheffield and even at Haworth, it may hardly reach 5 feet 6 inches. The causes of this great degeneration are manifold: some of them may easily be traced; but either the will or the power to remedy the evil is wanting.

Of the moral and intellectual endowments of Yorkshiremen, it may perhaps appear presumptuous or invidious to speak; but the subject is too interesting to be passed by in silence, and I will endeavour to treat it without either "extenuating, or setting down aught in malice." In few parts of Britain does there exist a more clearly marked moral type. To that of the Irish it has hardly any affinity; but the Scotchman and the Southern Englishman alike recognise the differences which distinguish the Yorkshire character from their own, but are not so apt to appreciate the numerous respective points of resemblance. The character is essentially Teutonic, including the shrewdness, the truthfulness without candour, the perseverance, energy, and industry of the Scotch, but little of their frugality, or of the theological instinct common to the Welsh and Scotch, or of the imaginative genius, or the more brilliant qualities which sometimes light up the Scottish character.

The sound judgment, the spirit of fair-play, the love of comfort, order, and cleanliness, and the fondness for heavy feeding are shared with the Saxon Englishman; but some of them are still more strongly marked in the Yorkshireman, as is also the bluff independence—a very fine quality when it does not degenerate into selfish rudeness. The aptitude for music was remarked by Giraldus Cambrensis seven centuries ago; and the taste for horseflesh seems to have descended from the old Norsemen, though it may have been fostered by local circumstances. The mind like the body, is generally very vigorous and energetic, and extremely well adapted to commercial and industrial pursuits, as well as the cultivation of the exact sciences; but a certain defect in imaginative power must, I think, be admitted, and is probably one reason, though obviously not the only one, why Yorkshire, until quite modern times, was generally behindhand in politics and religion, and why the number of her sons who, since Cædmon, have attained to high eminence in literature is not above the average of England.

ON MEDICAL STUDIES

AS at the present time so many students have just assembled at the medical schools in London and the provinces to commence or continue their medical education, we think that notwithstanding the advice so freely given them in all directions by their friends, and especially by those who deliver the introductory addresses at the different hospitals, there are some few points to which their attention cannot be too frequently directed

First, with regard to the range of subjects which is required by the higher examining boards, such as the University of London, in the earlier stages of the medical curriculum. There cannot be the least doubt, though several who have not participated in its advantages are fond of expressing an opinion to the contrary, that the wider and more extended the field of study that can be grasped by a student at the outset, the more chance he has of ultimate success; and he who has no higher object in view than that of passing the least difficult of the necessary examinations which give him a licence to practise, must ultimately find himself far behind in the race. In surgery, no doubt, there are a few who, without much scientific knowledge, have attained great eminence as operators, on account of their manual dexterity; but this position ought not to be the aspiration of the commencing student, as the reputation is generally of short duration, and is not much higher than that of a man who has rowed in a winning University boat-race.

One great argument in favour of a liberal medical education is that the mental capacities of the young men who commence it are very different; and if those who are the most gifted have but little chance of acquiring a knowledge of the facts and theories of Science, as they stand at the time at which they study, they are placed in a position of disadvantage for future research, and find it always difficult to make up for lost time. When all have to start on the extended course, which includes a knowledge of physics, botany, pure physiology, and chemistry, those who have the capacity for higher work in Science obtain an opportunity of developing their tendencies, and are often led to give up their original design of being medical practitioners, to become specialists in their favourite subjects, and an honour to Natural and Medical Science. This means of selecting the best men for scientific work would be a sufficient result in itself to justify the primary education of all medical students in the pure sciences that relate indirectly to medicine; for it must be remembered by those who hold the contrary opinion, that it is to its scientific supporters that the medical profession owes most of its dignity. If we look at the names of those who stand highest in the profession at the present day, it is readily seen that nearly all have their reputation based on a thorough scientific foundation. The lowering of the scientific standard would, therefore, undoubtedly lower the status of the profession amongst society at large, and it will be generally acknowledged that such a result is anything but desirable.

The recent thorough working out of the cause of the outbreak of typhoid fever in the west end of London this summer, shows how satisfactory are the results which follow the employment of a rigorous scientific method of observation. How long it would have remained undiscovered that the impurities in the milk-supply of a locality are the not unfrequent cause of an outbreak of typhoid fever it is impossible to say, if the subject had not been entered upon and carried through in a manner which does great credit to those who detected its origin, as Dr. Ballard had done on a former occasion in Islington.

A second point worthy of attention is the social position of the medical student. That he generally does not compare favourably with the undergraduates of Oxford and Cambridge is certain; but why this is the case does not seem to be so definitely settled. One of the great reasons is that the medical education does not include anything but the mental training: and although the medical student is like the average University undergraduate so far as age, preliminary education, and object of life are concerned, nevertheless after a curriculum of three years or more, the latter has made more progress as a social individual. The different natures of their studies cannot be proved to have anything to do with the difference in the results, and nearly all may be traced to the systems in which each participates. The University undergraduate is subject to two independent influences for good. A fixed code of University and College rules restrains him in many directions, as with regard to his conduct and the allotment of his time; at the same time that a much more stringent, but not written code, the result of his necessarily intimate relations with a large number of companions of his own age, regulates the details of his actions continually, the infringement of which code removes him from his most pleasurable source of enjoyment during leisure hours. Most medical students miss both of these. The absence of a Proctorial system and College rules makes him free to his heart's content; and the comparative smallness, as a rule, of the clique to which he belongs, helps to encourage rather than remove objectionable individual peculiarities, which would not be tolerated in general society. It is excessive freedom which is the bane of the young medical student, and the introduction of any system which provided a reasonable amount of restraint during the medical education would undoubtedly improve the social status of its undergraduates. Attempts have been made, but on too small a scale to be really successful. If the leading schools could be persuaded to invest money in building suitable apartments for their pupils, and spend part of the profits which must necessarily accrue to them, in giving scholarships, open only to those who resided in such buildings, a system might be developed which, after some time, from the convincing evidence it would give of its advantages, would cause all to participate in it.

Until there is much more co-operative feeling among the different schools in London, it is difficult to conceive how this or any other really marked improvement can be effected. Whilst things stand as they do, we are convinced that, in the long run, those will enjoy the most profitable studentship, and afterwards find themselves in the most advantageous position, who put themselves under reasonable restraint, and endeavour to extend their circle of acquaintance beyond the few sympathising "chums," who generally have but little influence for good, at the

same time that they often, by an unconscious process of approval and persuasion, help to exaggerate bad qualities and develop worse.

LYELL'S "ANTIQUITY OF MAN"

The Geological Evidences of the Antiquity of Man, with an Outline of Glacial and Post Tertiary Geology, and Remarks on the Origin of Species, with special reference to Man's First Appearance on the Earth. By Sir Charles Lyell, Bart., M.A., F.R.S. Fourth Edition Revised. Illustrated with Woodcuts. (London: John Murray, 1873.)

SINCE the first volume of "The Principles of Geology" appeared—now more than forty-three years ago—Sir Charles Lyell has put forth an uninterrupted series of new works or new editions, and we have now arrived at the 11th edition of the "Principles," the 7th of the "Elements of Geology," and the 4th of the "Antiquity of Man." A most striking feature of these works is, that they give the fullest and most accurate scientific details, and the most philosophical discussion of principles and results, without for a single page ceasing to be interesting to any well educated and thoughtful man. Perhaps no author has attained in so perfect a degree the art of making science popular without ever attempting to popularise it, or has produced a series of works which are equally acceptable to the experienced geologist and to the general reader.

The present edition of the well-known "Antiquity of Man" will fully sustain the author's high reputation, since it is not a mere corrected reprint of former editions, but, in several important respects, a new work, embodying all the most recent discoveries and researches on the various subjects of which it treats, while several discussions of temporary or personal interest have been omitted. Almost every chapter contains either important new facts or new results derived from a more careful study of old ones; while some are almost wholly rewritten, as, for example, chap. xii., in which the most recent researches on the climate of the Crag period is very fully given; and it would need a very acute critic to discover in these any lack of that lucidity of arrangement and vigour of thought which have always distinguished Sir Charles Lyell's writings.

The most striking additional facts bearing directly on the Antiquity of Man are so well known and have been so often before the public, that it is unnecessary to enumerate them here; but it may be advisable to remark briefly upon a theoretical point of some importance on which the author's views seem open to question; and there are also a few matters connected with the general subject which seem worthy of attention.

Although Professor Gastaldi, of Turin, after a careful study of the Italian Alps, has adopted Professor Ramsay's view of the excavation of alpine lake basins by ice, Sir Charles Lyell is still strongly opposed to that view. He maintains that they have been produced by changes of level in valleys, producing depressions which have been preserved during the glacial epoch by being filled with ice, while at all other times they were either soon filled by *débris*, or their lower barriers were cut down as fast as they were formed. He thus accounts for the fact that lakes only occur in any abundance in glaciated districts. He further maintains that the erosive power of glaciers, as indicated by the muddy torrent that always issues from them has been overrated, because "the flour of rock" thus produced is due, not solely to the wearing down of the floor of the valley, but, "to a considerable extent," to the grinding up of the stones which fall upon the glacier and are engulphed in its crevasses.

There are doubtless many difficulties in Prof. Ramsay's theory, and much remains to be done to verify it, but it does seem to cover a larger portion of the facts than that now opposed to it. There is no evidence before us to show how much of the glacier mud is respectively due to the two sources above referred to, but the enormous bulk of many of the old moraines, where they have not been destroyed by subsequent denudation, seems amply sufficient to account for the *débris* which falls upon a glacier; while the wide extent of glaciated surfaces, and the manner in which the very hardest upturned strata are often planed off or *moutonnées*, is equally convincing proof that large masses of rock have been ground down by glaciers. The evidence of this is very remarkable also, in the case of the Loess, a deposit which covers an enormous extent of country, and in some parts of the valley of the Rhine reaches a thickness of near 1,000 feet, and which Sir Charles Lyell himself considers to be undoubtedly glacial mud. It is difficult to conceive how such an enormous amount of mud could have been formed except by a grinding power capable of producing most of the effects imputed to it by Prof. Ramsay. It is considered to be one of the most powerful arguments against the ice-erosion theory that no lakes exist in certain valleys which were undoubtedly filled with enormous glaciers; but the answer to this is, that a lake will only be produced when the erosion is considerably greater at one part of the valley than at another, and this inequality may be caused either by unequal hardness of the subjacent rocks or by the piling up of the ice to a greater thickness in certain spots by the convergence of several branch glaciers, as must have been notably the case over the site of Lago Maggiore, which received the icy streams descending from near 100 miles of the loftiest Alps. It must also be remembered, that at such points of convergnce the rate of motion of the glacier will be much more rapid than elsewhere, in order to discharge the accumulated ice-streams; and we shall thus have a double cause of increased grinding in such positions. A difficulty of a somewhat similar nature, and which cannot be so easily overcome, besets the unequal-subsidence theory, which can hardly be made to account for the thousands and tens of thousands of lakes so thickly scattered over the lowlands of Northern Europe and America.

It is somewhat remarkable that notwithstanding the numerous researches in post-tertiary caves and gravels in all parts of Europe, no human remains have been discovered which can be proved to be older than those found by Dr. Schmerling more than forty years ago in the caverns near Liége. After many years' labour this gentleman, a skilful anatomist and palæontologist, published, in 1833, a detailed account of his researches, copiously illustrated. It is curious to see, from Sir Charles Lyell's account of this work, how completely its author antici-

pated all the more important results of modern cave exploration, and how thoroughly he had worked out that doctrine of the antiquity of man which the great majority of geologists so long attempted to put down. Such wholly independent researches as those of Schmerling in Belgium, McEnery in Devonshire, and Boucher de Perthes in France, made by careful and conscientious observers, and all converging to the demonstration of one fact, were for many long years laughed at or ignored, solely because they clashed with preconceived opinions. When this occurred with the students of a science which had already fought and won many hard battles against popular and theological prejudice, and whose whole course of study should have taught them how to interpret the evidence adduced, we are bound to deal tenderly with the less unjustifiable prejudices of those who have had no such training.

Notwithstanding the lesson these long-ignored facts should have taught them, some geologists still exhibit a strange fear or hesitation in facing the whole results of modern inquiries on the subject. How is it that, whenever any estimate is made of the lapse of time (expressed in years) since any human remains or works of art were deposited, the lowest possible estimate is almost always chosen? One would think that, having once got beyond the traditional six thousand years, the period of man's past existence would be a matter of purely scientific inquiry, to be arrived at by careful estimates in a variety of ways. But how can we possibly arrive at the truth by always taking the lowest estimate? we might just as reasonably always take the highest. Is there any merit in arriving at a false result so that the figures are small? Is it really the "safe" side so to calculate that we shall almost certainly be wrong? Astronomers do not think those observations most likely to be correct which give the smallest distances and sizes of the heavenly bodies and it would be more dignified and more scientific if geologists, whenever any data exist on which to found a calculation, should insist on taking the mean result of various impartial estimates as that most likely to be the true one. From this point of view it may be interesting to give a summary of the more important attempts which have yet been made to determine the antiquity of human remains or works of art.

From observations at the delta of the Tinière and on the lakes of Neufchatel and Bienne, the bronze age in Europe has been determined with approximate accuracy to have been from 3,000 to 4,000 years ago, and the stone age of the Swiss Lake dwellings at from 5,000 to 7,000 years and an indefinite anterior period. The burnt brick found 60 ft. deep in the Nile alluvium indicates an antiquity of about 20,000 years, taking, from a calculation by Mr. Horner, the estimate of $3\frac{1}{2}$ in. per century as the rate of deposit of the mud. Another fragment found at 72 ft. deep is estimated by M. Rosière to be 30,000 years old. Some human bones found in a lacustrine formation in Florida have been considered by Agassiz, after a careful examination of the locality, to be at least 10,000 years old. A human skeleton found at a depth of 16 ft. below four buried forests superposed upon each other, has been calculated by Dr. Dowler to have an antiquity of 50,000 years.

These latter estimates may be very uncertain, but we have no reason to think them improbable, from what we know of the great changes of physical geography that have undoubtedly taken place since man existed. Kent's Cavern at Torquay furnishes a good example of these, since the whole drainage of the surrounding country must have been very different when the great thickness of cave earth was deposited by floods rushing through the cavern which is now situated in an isolated hill. We have here indications of an immense antiquity from various sources. The upper stalagmitic floor itself marks a vast lapse of time, since it divides the relics of the last two or three thousand years from a deposit full of the bones of extinct mammalia, many of which, like the reindeer, mammoth, and glutton, indicate an arctic climate. It has been remarked that the varying thicknesses of the stalagmitic floor, from 16 in. to 5 ft. and upwards, closely correspond to the present amount of drip in various parts of the cave, so that the cave itself with its various fissures and crevices does not appear to have been materially altered since the stalagmite was deposited. It is true that the drip may once have been greater, but it may also have been less, and we do not know that a more copious drip would necessarily produce a more rapid deposit of stalagmite. But names cut into this stalagmite more than two centuries ago are still legible, showing that, in a spot where the drip is now very copious, and where the stalagmite is 12 ft. thick, not more than about one-eighth of an inch, or say one-hundredth of a foot, has been deposited in that length of time (British Association Report, 1869, p. 196). This gives a foot in 20,000 years, or 5 ft. in 100,000 years; and there is no reason whatever to consider this to be too high an estimate to account for the triple change of organic remains, of climate, and of physical geography. But below this again there is another and much older layer of stalagmite, generally broken up and imbedded in the cave earth. This older stalagmite is very thick and is much more crystalline than the upper one, so that it was probably formed at a slower rate. Yet below this again, in a solid breccia, very different from the cave earth, undoubted works of art have been found. A fair estimate will therefore give us, say, 100,000 years for the upper stalagmite, and about 250,000 for the deeper layer of much greater thickness, and of more crystalline texture. But between these we have a deposit of cave-earth which implies a different set of physical conditions and an alteration in the geography of the surrounding country. We have no means of measuring the period during which this continued to be formed, but it was probably very great; and there was certainly some great change in physical conditions during the deposit of the lower stalagmite, because the fauna of the county underwent a striking change in the interval. If we add 150,000 years for this period, we arrive at the sum of half a million as representing the years that have probably elapsed since flints of human workmanship were buried in the lowest deposits of Kent's Cavern. It may be objected that such an estimate is so loose and untrustworthy as to be altogether valueless; but it may be maintained, on the other hand, that such estimates, if sufficiently multiplied, are of great value, since they help us to form a definite idea of what kind of periods we are dealing with, and furnish us with a series of hypotheses to be corrected or supported by

further observation, and will at last enable us to arrive at the antiquity of man within certain probable limits of error. Without laying stress on any portion of the above very rude estimate, it may, I think, be averred that it is not palpably too high, but is just as likely to be too low; and this last supposition will be rendered more probable when we consider the vast lapse of time implied by the position of some of the recently discoverd palæolithic weapons.

The flint tools found in the gravel at Bournemouth, in the Isle of Wight, and near Salisbury, at elevations of from 80 to 100 feet above the present valleys, imply, according to the best observers, that the whole series of surrounding river valleys have been excavated since they were deposited, and that the system of drainage and position of the coast-line have been very greatly altered. The hippopotamus of the Gower Caves implies changes equally great, since the peninsula of Gower now contains only small streams, and could not possibly have had a large river without very important changes in its relations to the adjacent country. The position of the flint weapons in the valley of the Somme, at Hoxne in Suffolk, and in many other places, all combine in indicating that very important changes in physical geography have taken place since they were deposited. We can hardly suppose that in all these different localities the changes were abnormally rapid, especially as in no case do records of the historic period indicate that any remnant of the process was then going on; and from what we do know of the rate of such changes, and their intermittent nature, we are entitled to affirm that the most extreme estimates yet made of the antiquity of the men who fashioned and used the palæolithic implements is quite as likely to be under as over the truth.

There is as yet no clear evidence that man lived in Northern Europe before the glacial epoch, and even if he did so the action of the ice sheet would probably have obliterated all records of his existence. Every evolutionist, however, now believes that he must have existed far back in the tertiary period, and that the proof of it will be found, if at all, in some of the warmer regions of the old world. Here is surely a problem of grand and absorbing interest awaiting solution at our hands. Geologists are not usually wanting in energy or enterprise, and they number in their ranks many wealthy men. It is to be hoped that they will soon energetically attack the problem; and no more promising field of research offers itself than the limestone caves of Borneo, which can be explored with perfect safety, and at a moderate expense. We can hardly now expect any great additions to our knowledge respecting the antiquity of man in Northern and Central Europe, and must go to warmer regions if we wish for new discoveries and startling revelations.

Fellowship at Magdalen College

I THINK the notice in NATURE of Sept. 25 respecting the election about to take place to a Natural Science Fellowship at Magdalen College requires some comment. The amount of academic preferment which falls to the share of science in Oxford is so small, that it might reasonably be demanded that what there is should be thrown open to as many candidates as possible. When, therefore, it was announced that the Fellowship would be given for proficiency in Biology, it might have been inferred that the electors had this object in view. Biology is held, elsewhere than in Oxford, to be the science which treats of the laws governing organization and vital activity; in other words, structure and function in *all* forms of life, whether vegetable or animal. It was not, perhaps, an unreasonable inference, therefore, to draw from the terms of the notice, that it was the intention of the College to make Biology in its widest sense the foundation of the examination, and to allow individual candidates to exhibit, in addition, such detailed knowledge as they might possess of Zoology, Botany, or even Palæontology. This would not have attributed to Biology a wider meaning than, for example, Mr. Herbert Spencer or the Science and Art Department attach to it. Thinking it desirable, however, to get some official information upon the subject, I wrote to the President, who, after some delay, replied that, in his opinion, as preference would be given to Biology, it would be useless to offer Botany as a special subject. This is not more reasonable than it would be to say, that because Physics was to be the subject of an examination it would be useless to offer Electricity or Heat as a special subject. But the terms of the President's reply were rather ambiguous, and I therefore made some further inquiries. I learnt, as the result, that the College considered it impossible to compare the merits of a candidate who stood on the Zoological, with one who stood on the Botanical, side of the general subject.

I think myself the difficulty is not one which should have been found insuperable; but, assuming that the College had sufficient grounds for a different opinion, then I think the electors should not have offered their Fellowship for Biology, when what they really had in view appears to be a detailed knowledge of the Zoological preparations in the University Museum.

W. T. THISELTON DYER

The Sphygmograph

THERE appears in NATURE, vol. viii. p. 330, a notice of a thesis for the M.D. Cantab. on the subject of Bright's disease, in which reference is especially made to some sphygmographic observations therein contained. It is apparently from the pen of Mr. Garrod, who is himself the author of interesting and important researches with the sphygmograph and cardiograph. While agreeing with a part of my explanation of the normal pulse tracing, as regards the points in which it differs from the view commonly received, he takes exception to the account which I have given of the tidal or first secondary wave. It may be well to say in reply a few words upon the point at issue, since the reference to it in the thesis was very brief and incidental, and I should not wish it to be taken as a full account of my views as to the mechanism of the pulse.

The explanation of Mr. Garrod himself is that the tidal wave is an instantaneous wave due to the closure of the aortic valves. This theory was first proposed by M. Marey to account for the tidal wave in many of its forms; but, so far as I know, it has not been adopted by any writer on the subject in England with the exception of Mr. Garrod. There is this difference, however, between them, that while M. Marey holds that the dicrotic wave has nothing to do with the aortic valves, but is a reflection from the periphery, Mr. Garrod considers that it is the wave of expansion from the closure of the aortic valves, which becomes separated from the instantaneous wave as it recedes from the heart. Thus the faculty of originating two waves of different velocity, which by most writers is attributed to the first impulse of the heart, combined with the closure of the mitral valve, is by Mr. Garrod denied to that event, but ascribed to the closure of the aortic valves. Now I believe it to be mechanically impossible for any wave to be propagated with a velocity different from that of the wave of expansion, except the purely vibratory wave of sound, and Mr. Garrod appears himself to hold that a mere vibration produces no elevation in the tracing. The question, however, may easily be determined experimentally. If there appear in the tracing two waves which are travelling with different velocities, their relative position will vary at different distances from the heart. Let, therefore, anyone who wishes to settle the question for himself take tracings of a good many

markedly tricrotic pulses, say from the femoral and also from the dorsalis pedis arteries. According to the view of Dr. Burdon Sanderson and most other writers, the interval between the primary and tidal waves ought to be more than doubled in the dorsalis pedis; according to the view of Mr. Garrod, on the contrary, that between the tidal and dicrotic waves. It will be found that there is no such considerable and constant variation as would be required by either theory, although the tidal wave does not maintain its relative position so closely as does the dicrotic wave. The kind of pulse best of all suited for this experiment is fortunately * rather scarce; it is that of a young person who has a granular kidney, but is free from dropsy.

The theory of Mr. Garrod may appear at first sight suitable to one of the forms of healthy pulse, in which the tidal wave appears as a slight elevation preceding the dicrotic wave; but I do not think that it will be accepted by anyone who has watched its variation in a large number of diseased pulses, and has seen it pass through every gradation, from a separate and distinct wave to a mere convexity in the descending curve, which may commence immediately from the top of the primary upstroke. In the pulse of rigid arteries this latter form is often taken when the heart is quiet, but when it acts more vigorously the tidal wave becomes separated, owing to the development of the so-called "percussion element," which is really the effect of acquired velocity in the sphygmograph. The case which should afford the most crucial test is perhaps that very rare one in which the aortic orifice is closely obstructed, and scarcely any valves remain to produce a wave by their closure. The tidal wave should then, according to Mr. Garrod's theory, be at least greatly diminished, but, in point of fact, it is then more greatly developed than under any other circumstances whatever. Evidence to the same effect may be derived from the use of an artificial heart with experimental elastic tubes, for it is found that, under suitable conditions, the tidal wave may be greatly prolonged by a protracted contraction of the heart. This was first shown by Mr. Mahomed in the *Medical Times*, and although I believe his theory to be erroneous as to the relation between the primary and tidal waves, yet, with regard to the practical associations of the tidal wave, my experiments have led me to conclusions which are quite in agreement with his, namely, that three things contribute to the development of the tidal wave—increase of pressure, diminution of elasticity, and prolongation of the heart's contraction.

Mr. Garrod argues that the tidal wave cannot have anything to do with the inertia of the long lever, because it is shown in the reflecting sphygmoscope, in which that is absent. I do not, however, consider that the result is due solely, and possibly not even chiefly, to the inertia of the lever, but to that of the instrument altogether, and inertia is possessed likewise by the sphygmoscope. Moreover, since the latter does not record its indications, it would be difficult to ascertain whether the tidal wave shown by it corresponds precisely to that of the sphygmographic tracing. Another instrument has also been called a sphygmoscope, in which the motion of the pulse is shown by the variation of a gas flame. In this there appears indeed the counterpart of the tidal wave, but not in the form of a single wave; instead of this a series of small waves is shown. These may appear only as a slight quivering motion, and are evidently due to the oscillation of the elastic diaphragm upon which the pressure of the pulse is received.

Mr. Garrod maintains his own theory especially on the ground of observations with his cardio-sphygmograph, showing the commencement of the tidal wave in the radial pulse to be synchronous with the closure of the aortic valves. But the determination of the moment of that closure depends on the correctness of his interpretation of the minor elevations in the cardiographic tracing. These are numerous, and his interpretation of them all is most ingenious, but to accept it requires an implicit faith that the instrument itself has no part in producing any of the minor features of the curve. Now, that curve was drawn by a lever, moving on a pivot, and balanced between two springs, which would seem a contrivance peculiarly liable to oscillate. When therefore it is further found that in cardiac tracings published by other observers, or those obtained by applying the sphygmograph directly to the heart, there is no close correspondence either in the number or the position of the elevations, the conclusion can hardly be resisted that some of them are due to such oscillation. My own opinion is that neither in the cardiographic nor in the radial pulse tracing can the point corresponding to the end of systole be precisely determined.

The whole subject is one which it is difficult even to state intelligibly without a constant reference to diagrams of tracings, and therefore, for a fuller account of my views as to the theory of the pulse, particularly in reference to the complete explanation of the dicrotic wave, I must refer to a paper to be published in the next number of the *Journal of Anatomy and Physiology*.

While I consider that the construction of the sphygmograph has some influence on the tracing produced, yet I believe that, by a fortunate chance, the result is more practically useful than if the pulse-wave were recorded with perfect accuracy, for I think that slight differences in it, which would then perhaps escape notice, are, as it were, magnified and made manifest to the eye.

I may say in conclusion that I do not quite agree in the view that we must wait for the practical application of the sphygmograph until physiologists are agreed about the theory of the pulse, for, according to present appearances, that consummation is distant indeed. There is, however, among sphygmographers an agreement about practical inferences which is almost as notable as the confusion which prevails as to mechanical causes. It is possible therefore for a person to use the sphygmograph for diagnosis and prognosis, who does not even attempt to understand the cause of the waves seen in its tracings. But it must be allowed that the settling of the mechanical question is much to be desired, and that, without it, the sphygmograph cannot afford that service, which otherwise it would be capable of doing, to the solving of all general physiological problems relating to the vascular system. And, from a practical point of view, these may perhaps be regarded as among the most important in physiology, for it is probably through the agency of the vascular system that many of the greatest effects of remedies are produced.

A. L. GALABIN

On the Origin of Nerve-Force

IN a paper on this subject, by Mr. A. H. Garrod, in NATURE, vol. viii. p. 265, the author states that in cold-blooded animals, nerve-force must be generated by the difference between their own temperatures and that of the medium by which they are surrounded. Now, to take the case of a frog as a common example of a "so-called" cold-blooded animal: A few days ago, when the thermometer was standing at 71°, I took the temperature of two frogs, one was 69°, and the other 67°; the difference between their temperature and that of the surrounding air was practically *nil*. Now, on a day of this sort of temperature, it would seem that the pervious integument of the frog is continually exhaling moisture, and that in consequence the temperature falls, and would continue to fall below that of the surrounding air, were it not that it was raised by the heat generated "by the destruction of tissue that is continually going on within the body of the animal;" so between these two contending forces a state of equilibrium results, and the temperature of the animal and the surrounding air are the same. But, if this be true, it follows that the whole of the heat from the animal is used up in keeping up its temperature, and therefore none can be spared for conversion into nerve-force. Therefore, a frog at rest on a summer's day ought to have no nervous energy. Now, suppose our frog takes to leaping vigorously, he will develop a certain amount of heat, and then he ought to have a great deal of nerve-force; but it is not found that an active frog is more "nervous" than a quiescent one.

Again, the nervous irritability of a frog, though perhaps not acting with the instantaneous energy with which it acts in a mammal, still persists far longer than in other vertebrates, and will continue much longer after the somatic death of the animal, when it is quite clear that the temperature of the body and the surrounding medium will be the same. Now in this case the nerves may be so irritated as to lose all irritability, and yet, after a period of rest, this irritability will be regained, clearly, to my mind, showing that nervous energy must be generated after the death of the animal, when all differences of temperature have ceased.

Finally, it must be admitted, without the aid of any hypothesis, that the difference between the temperature of a frog and the surrounding air is, at any time, very slight; and yet this animal possesses what we call an extremely "persistent" form of nerve-force.

R. LYDEKKER

On the Polarisation of Light in the Rainbow

As I do not remember seeing any notice, in books on light and colour, about the polarisation of light in the rainbow, I think it my duty to relate the following facts, although I can scarcely think the appearance has been unobserved till now.

Three times I have tested the rainbow-light this summer, and each time I found it wholly polarised. On the first occasion, while looking at the rainbow, I thought I would examine it with a tourmaline, which I kept in my pocket. I looked at the bow, through the tourmaline, and saw the bow; but on rotating the tourmaline the bow alternately disappeared and reappeared at every quarter turn: while the light from a stack of chimneys which stood within the bow remained apparently unchanged. From this I inferred that the light of the rainbow was wholly polarised, while the other light in its neighbourhood was not so.

I have observed the vanishing and reappearing of the light of the rainbow on rotating the tourmaline on two occasions since that. I have waited for these additional occasions to make sure of the fact, as I was called away from the first observation; and when I could go back the rainbow had vanished.

The date of the second and third times are August 28 and September 4, 1873.

Leicester, Sept. 5 GEO. FINLAY

[The polarisation of the light of the rainbow was observed by Biot in 1811, and by Brewster in 1812. (See "Brewster's Optics," art. 185.) With respect to rainbows by reflection, there are two kinds—(1) that observed by X. Z. Y., in which the light comes to the eye from the water. This is not thought worthy of special mention by Brewster. (2) That in which the light of the sun reflected from water strikes the shower and forms a bow not concentric with the common bow. (See "Brewster's Optics," art. 186.) It is very easy to see that these two kinds of bow form parts of the same cone whose axis is at the same altitude as the sun, but in the opposite azimuth.—J. C. M.]

Autumnal Typhoid Epidemics

THERE appear to be two types of these,—first, the malignant and dangerous, which breaks out in isolated spots and is usually traceable either directly or indirectly to some sins of sewerage; and a second or milder form, which extends over far larger areas, is much more general, and apparently unconnected with sewage exhalations or liquid contaminations. Some observations I have lately made suggest an explanation of the origin of this latter form. We have had just a moist and rather warm summer, followed by an unusually wet autumn. Turnips, swedes, beets, mangolds, cabbages, potatoes, peas, &c., put forth luxurious foliage, and much of this, especially the lower leaves of turnips, swedes, and cabbages, have been rotted by the recent rains—so much so, that many a country lane that should have exhaled sweet balmy odours has been the abode of most unromantic stink. This is especially the case in the flat market garden areas that lie by the side of the Thames, and in these the most especially where cabbages are cultivated. I have no doubt that the partridge shooters of 1873, who have largely availed themselves of the cover of turnip-fields, will confirm my observation of their offensive odour.

Modern agriculture is, in England, chiefly developing and extending in the direction of root crops for cattle feeding, and the foliage of these is very liable to offensive decomposition under the conditions above named. When the autumn is hot and dry, their outer leaves, and also those of kitchen vegetables, drop off and return to the soil in a dry, crisp, and inodorous condition.

That the moist decomposition of such vegetable matter should supply nourishment to disease germs analogous to those which are fed by sewage, and that the exhalations of the decomposing vegetables should spread them after the manner of sewage exhalations, is obviously probable.

If I am right, the widely extended and milder forms of autumn epidemics should be most prevalent in such years as the present, and should prevail more especially in market-garden and cattle-feeding districts.

So far as my own means of observation extend, this appears to be the case, but as these are too limited to justify any positive conclusion, I throw out the above as a merely suggestive explanation, demanding further confirmation, which some of the readers of NATURE may be able to supply.

Woodside, Sept. 8 W. MATTIEU WILLIAMS

Venomous Caterpillars

OBSERVING a letter in NATURE respecting venomous caterpillars, I venture to offer a few remarks from personal experience.

The rough hairy caterpillars have a bad reputation everywhere. As a boy, the nurses told me if one got tight round my finger, *it* (and of course I understood the finger) would have to be cut off. In Switzerland they are regarded by the common people as poisonous, though, as far as I know, without foundation.

In Portugal there is a most remarkable gregarious species, known as the "procession caterpillar," from the great numbers that may be seen advancing in a body. This kind has undoubtedly the power of causing very considerable irritation to a tender skin. A specimen once crawled up the arm of my little girl, then one year old, leaving the skin-surface red and inflamed along its track; and there was a tradition at Lisbon of a child that had fallen into a mass of these larvæ, and subsequently died from the consequent inflammation.

In Brazil there is a species in the neighbourhood of Rio that, with regard to the formidable nature of its external clothing, is a veritable porcupine. It corresponds remarkably with the description of the Burmese specimen, both in size and colour. The hairs, in a state of repose, are, however, but slightly erect, and it is only when irritated or alarmed that it raises them in hostile guise. There can be no question as to the stinging properties of these hairs, to which my wife, among others, can bear testimony; but as our experimental ardour did not induce us to grasp the creature, the consequences were never serious. The largest hairs must be nearly an inch long, and the points of all have a lighter appearance, as though singed. It was interesting to watch their elevation by the animal on the approach of the finger, as though by some electric attraction. The stinging sensation is analogous to that caused by a nettle. I am inclined to think that in this case the cause was likewise analogous. It is, however, possible that the hairs are brittle, or armed with articulated branches.

With reference to the power of detaching hairs possessed by some caterpillars, a remarkable instance came under my notice in Tiguca (Brazil). It was observed in the larva of a beautiful black and white butterfly with conspicuous yellow tail. The determining principle of its existence appeared to be rather economy than defence. Consequently the hairs with which its body was covered were utilised in the construction of its cocoon. For this purpose it was first clearly necessary to shed them; after which they were dexterously crossed and recrossed over the creature's body ensconced under the shadow of some convenient leaf. In this process, if thread was used at all, it was with the greatest economy.

As it was evident that such hairs must be well adapted to their purpose, I examined them under a good microscope, when I found them armed with short barbs on all sides, especially towards the extremities. The spines were tolerably thick, giving under the lens much the appearance of a sprig of juniper.

Berne, Switzerland C. EDEN

IN reference to the article on venomous caterpillars in NATURE of the 14th inst., I beg to offer you, if the subject is not closed, my own very unpleasant experience.

On the 19th of June last, as I was sitting in my drawing-room near an open window, looking on the garden, I suddenly felt an itching sensation in my throat and arm, and on examining my dress I found a large brown long-haired caterpillar. In a few moments my skin, on the parts affected, was covered with a strong eruption attended with intense heat. Thinking it impossible that the insect could have produced this inflammation, I sent for a doctor. After examining the skin he assured me he could see no other cause, and that the eruption resulted from the hairs of the caterpillar remaining in the skin.

He ordered me some simple applications, telling me that a few hours would bring relief. In this he was totally mistaken. The inflammation increased to the extent of producing general fever; I passed a sleepless night, and the next day it continued unabated. After that it very gradually subsided, but the traces of the eruption were visible ten days afterwards.

The insect could not, I imagine, have bitten me, as I felt nothing at the moment.

I have frequently been bitten by tropical insects, but in no one instance have I suffered so severely, or been so disfigured. The sensation reminded me somewhat of the prickly heat, only it was infinitely more intolerable.

There was no predisposing cause, as I was at the time in good

health, and had no tendency to fever, although the temperature was remarkably high for the month of June.

I have not seen a similar accident during my fifteen years' residence in France, but I presume they are not unfrequent here, or there would be no reason for the vulgar French expression "Mauvaise comme une chenille." A. GILLANDER

7, Rue St. Claire, Passy, Paris

The Glacial Period

PROF. TYNDALL has several times called attention to a point in regard to the height of the snow-line, which seems to be steadily overlooked by those who speculate on the causes of the great prevalence of snow during the glacial epoch. It is of course well known that the height of the snow-line at any place is determined mainly by two things, viz., the depth of annual snow-fall, and the temperature of the place. If the amount of snow falling over the whole earth is to be increased, the evaporation must also be increased. ("Heat as a Mode of Motion," pp. 206-7. New York, 1866.) This would also raise the temperature, but the snow-line might nevertheless descend. We have a case of exactly this kind in the Himalayas. On the warm southern side of these mountains the snow-line is, nevertheless, 3,000 ft. lower than on the northern side, where the temperature is very much colder. This is evidently due to a difference in the amount of annual precipitation. Assume that the sun was at one time much warmer than now, and that since then it has been steadily cooling; and I believe you have the key to the solution of the questions asked by J. H. Rohrs, as well as to such questions as the widespread occurrence of tropical vegetation during the past ages.

Iowa City, U.S. FRANK E. NIPHER

RECENT RESEARCHES ON THE LOCALISATION OF THE CEREBRAL FUNCTIONS

THE fifth part of Dr. Brown-Séquard's new "Archives of Scientific and Practical Medicine" contains an excellent report by Dr. Neftel, "on some of the recent researches in neuropathology" embracing a digest of several important modern methods, recently introduced, for the purpose of analysing the functions of the different parts of the cerebral hemispheres, together with a succinct account of the results arrived at by their employment. An abstract of this report forms the substance of the present notice.

The researches of Longet, Magendie, Matteucci, and others have led to the assumption by most physiologists, that the cerebral hemispheres, especially their cortical substance, are destitute of sensibility, being the seats of origin of higher mental phenomena only. The experiments from which these conclusions were arrived at, consisted in the irritation of the hemispheres in living animals by mechanical, chemical, and electrical means; and in none were they succeeded by muscular contractions. As if to put the question beyond a doubt, Flourens removed the entire hemispheres without disturbing the muscular mechanism.

But the tendency of modern observation is in a different direction; the new researches have been made independently by several investigators, with entirely different methods, nevertheless the results are the same, contrary to that of the earlier workers; the evidence going to prove that the cortical substance of the cerebral hemispheres is in close relation with certain muscular groups, forming the "psychomotor centres" of Gudden.

Fritsch and Hitzig commenced these researches, the latter having observed that galvanic excitation of the hemispheres in the living man produced contraction of the eye-muscles. This aberrant result suggested further experiments. They irritated the cerebral hemispheres in a dog with an extremely weak current, and found that movements of certain groups of muscles followed the excitation of definite spots on the anterior convex portion of the brain, always upon the side opposite to that which was acted on; whilst the same excitation of portions of the hemispheres situated more posteriorily, produced no effect. Thus they found the centre for the extensor and adductor muscles of the anterior extremity at the external end of the pre-frontal convolution; and somewhat behind it the centre for the flexor and rotating muscles of the same extremity. The irritation of these centres by metallic closing of a very weak galvanic current produces a single contraction, whilst the interrupted current produces tonic and gradually disappearing contractions of these muscles, followed by epileptiform movements. The anode has much more influence in producing these results than the cathode, so much so, that with a current of minimal intensity contractions can only be produced by the anode.

When Fritz and Hitzig removed in dogs the centre for the anterior extremity, this latter did not become entirely paralysed, the animal could use it, but imperfectly, and seemed quite unconscious of the condition of the limb, which could be placed into any position without attracting its attention.

Nothnagel employs a new method for the determination of the functions of the brain. His observations are made mostly on rabbits. An incision is made in the scalp, the skull is perforated with a needle. Through the canal thus formed in the bone a very small drop of a concentrated solution of chromic acid is injected by means of a hypodermic syringe with a very slender nozzle. The scalp wound is then united by suture, and the animal does not seem to be affected, except with regard to the functional derangement incidental to the lesion. Generally they survive the operation two or three weeks, and die from causes which Nothnagel cannot explain, no constitutional symptoms being developed. However, when the chromic acid is injected into the lateral cerebral ventricles death is the immediate result. On post-mortem examination, where the chromic acid was injected a minute circumscribed place appears, of a green colour, resistant and hard.

In methods employed previous to this, many causes acted to impair the value of the results arrived at; there was considerable hæmorrhage, refrigeration of the brain surface, and modification of the intra-cranial pressure, in addition to which the animal died very shortly. These are obviated by the new means just described; many fresh facts have therefore been brought to light. In one of his experiments Nothnagel made a chromic acid lesion on the surface of the cerebral cortex, which penetrated very slightly into its substance, in a spot corresponding exactly to the outer end of the post-frontal convolution. The animal appeared healthy, but it was found on careful observation that it had lost the muscular sense in the anterior extremity, on the opposite side to the cerebral lesion, it being possible to put, and retain for some time, the affected paw in strained positions. This condition passed off before death, which seems to indicate that the terminal station or the real centre for the muscular sense exists elsewhere, and that after a time other ways to it become developed.

Nothnagel found, further, a circumscribed locality in the cerebral cortex, the lesion of which produces a partial and transient hemiplegia of the opposite extremity. This spot is in front of that for the muscular sense, and deeper than it. In no other portions of the cerebral cortex, except those above mentioned, have the chromic acid lesions been followed by paralytic symptoms.

Gudden has introduced another method by which the function of the different parts of the cerebrum may be studied. He finds that newly-born animals, as rabbits, will undergo a very great amount of mutilation without interfering seriously with the nutritive functions, so that portions of the brain may be removed, and the animal will grow to full size, with no peculiarities excepting those resulting from the absence of the parts removed. The slight sensibility, rapid coagulation of the blood, and the

quick growth, are all in favour of operations. The following are the results of his experiments on the cerebral hemispheres :—"Very convincing facts are obtained by removing the cerebral hemispheres in new-born animals, and allowing them to grow up. The result is idiotismus. There is also reason to locate the organic conditions of voluntary movements in the cortical substance of the brain, but there is no reason to accept the corpus striatum as a motor ganglion. The hemiplegion following the destruction of the nucleus lenticularis can be satisfactorily explained by the rupture of fibres passing through the internal capsule. But admitting the cerebral cortex as the organ for voluntary movements, there is no necessity to have another motor ganglion. Indeed, Gudden's experiments on new-born rabbits, by removing portions of the hemispheres, have demonstrated that the organ of voluntary motion is located in the frontal part of the cerebral cortex."

Dr. Ferrier, whose results are referred to in another column, is working in a similar field of observation, with the view of elucidating the relations between certain convolution centres, and definite sets of muscles at the periphery.

FRENCH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE

THE second meeting of the French Association for the Advancement of Science was held at Lyons from the 21st to the 28th of August, under the Presidency of Prof. Quatrefages. This Association bids fair to become as popular in France as the British Association in this country. The work done in the sections which I visited, those of Anthropology and Geology, was, to say the very least, as valuable as that done by our own sections. Among the papers brought before the former, the pleistocene station of Solutré excited considerable interest, and was subsequently visited by the section. The site has been used by man for habitation and burial, as late as the Merovingian times, in which it was a cemetery, and the strata are to a considerable extent *remanié*. The association of remains on that spot of varying age, Palæolithic, Neolithic, and Frankish, seems to throw a doubt on the precise date of the human skeletons, buried at full length, and generally believed to be of the same age as the associated implements of reindeer, and bones of mammoth. Dr. Gosse also read a paper on the reindeer-cave of Veyriers, Switzerland, and exhibited carved implements of reindeer antler, usually called "batons de commandement," which are of the same form as the arrow-straighteners of the Eskimos. Here, as in the caves of Belgium explored by M. Dupont, they presented but one perforation. The debates were very animated, and drew out many valuable remarks from the eminent anthropologist, Dr. Paul Broca.

In the Geological section, papers were contributed by the Comte de Saporta, MM. Dumortier, Beboux, and others, and in the debates Prof. Carl Vogt of Geneva took a prominent part. MM. Falsan and Chantre exhibited and described an elaborate map of the glacial phenomena of the middle basin of the Rhone, drawn on a large scale. They traced the glaciers of the Alps, and of the Jura, as far to the west as the Saône, and as far to the south as Valence ; and they proved that there were two epochs of glaciation, the one during which the area in question was covered by a great ice-sheet, conveying Alpine blocks over the Jura into the valley of the Saône and middle basin of the Rhone, and the other during which the glaciers were isolated, and local moraines accumulated in the river valleys. These two periods correspond with those which have been noted in Great Britain and Ireland, by Prof. Ramsay, Hull, and others. The map presented a combination of artistic skill, with careful work in the field, which is very rarely met with.

In the evening three popular lectures were given to the public, one of which, by M. Janssen, on the Constitution of the Sun, was admirably illustrated.

The times of meeting of the sections differ from ours, the programme of the day being, first, a morning sitting from 8.30, or 9 to 11 A.M.,—*dejeuner;* and, an afternoon sitting from 3 to 5 P.M.—then dinner ; and sometimes an evening sitting commencing at eight, when there were no lectures going on. The sections were 15 in number, and comprised Agriculture and Medicine, as well as those represented in the British Association. There were excursions down the Rhone, and to Geneva ; a grand *fête* given by one of the merchants, and a magnificent entertainment given by the City of Lyons in the Town Hall.

In writing this short notice the extreme courtesy and consideration of the French Association to the strangers should not be omitted. Their hospitality to the only English guest present was too great to flow from any personal motive, and evidently was intended as a mark of respect to the British Association. W. B. D.

THE METEOROLOGICAL CONGRESS AT VIENNA

THE Meteorological Congress which met at Vienna during the past month worked very hard amid many difficulties, and we believe will have good results. The Congress sat from Sept. 2 to Sept. 16. The protocols and appendices are in the press, and will appear officially in French and German ; while Mr. R. H. Scott has undertaken an English translation, which will appear as soon as possible. The following is a list of the delegates from the various countries :—Antonio Aguilar, Spain ; H. Buys-Ballot, Netherlands ; Carl Bruhns, Germany ; Alexander Buchan, Great Britain and Ireland ; J. D. Campbell, China ; Giov. Cantoni, Italy ; Aristide Coumbary, Turkey ; v. Czelechowsky, Austria ; F. Doergens, Germany ; Prof. Ebermayer, Bavaria ; Fradesso da Silveira, Portugal ; M. Gloesener, Belgium ; Julius Hann, Austria ; Hoffmeyer, Denmark ; Carl Jelinek, Austria ; Josef Lorenz, Austria ; Heinrich Mohn, Norway ; Robert Müller, Austrian-Hungary ; Albert Myer, United States ; Georg Neumayer, Germany ; E. Plantamour, Switzerland ; Ernst Quetelet, Belgium ; R. Rubenson, Sweden ; Guido Schenzl, Hungary ; Julius Schmidt, Greece ; H. Schoder, Germany ; Robert H. Scott, Great Britain and Ireland ; Carl Sohncke, Germany ; H. Wild, Russia ; F. Winnecke, Germany ; A. Zamara, Austria. The following is the programme of subjects discussed :—

1. *Instruments.*—1. What is the construction of the barometer most suitable for stations of the second order? Is the use of aneroids at such stations advisable? 2. What mode of exposure of thermometers for the observation of air temperature is the best and most suitable for general adoption? 3. What is the best construction for maximum and minimum thermometers? 4. What instruments should be used for determining intensity of radiation, and in what way can the comparison of the results obtained be secured? 5. What is the best apparatus for observing earth temperatures? At what depths ought they to be made, in order that the desired agreement may be attained? 6. What instruments should be used for ascertaining the state of moisture of the atmosphere? Does the psychrometer suffice for this purpose? Can the hair hygrometer be made applicable, and with what limitations? 7. In what way can an agreement in the signs for the directions of the wind be attained? Is the deduction of the mean direction of the wind according to Lambert's formula desirable? Is it desirable or not to include very light winds (force 0) in constructing wind roses for the direction of the wind? 8. What scale is to be used for the force of wind where it has to be estimated without the aid of an instrument? 9. Is the

introduction of simple counting instruments for ascertaining the rate of the wind desirable? What units should be fixed upon as a basis for observing the rate of the wind? 10. What is the most suitable form, size, and position for rain-gauges? At what time of day should the measurement of rainfall be made. 11. Should days of rain and snow-fall be separated from each other, or be counted as the same? 12. Is it desirable in recording the amount of hail to separate the falls of sleet (*graupel*) from those of hail proper? 13. In reckoning thunderstorms, are the storms only to be recorded, or the days in which they occurred? How is sheet-lightning to be regarded? 14. What apparatus is to be recommended for measuring evaporation? What is the most suitable exposure for the vaporimeter? 15. How should the amount of cloud be estimated and recorded? Is it desirable to introduce for clouds, hydrometeors, and for other extraordinary phenomena, a nomenclature which shall be independent of local language, and therefore universally intelligible? 16. Moreover, should other elements which are reckoned meteorological, *e.g.* atmospheric electricity, ozone, &c., be included in the circle of normal observations, and what are the most suitable instruments for observing them. 17. For meteorological measurements should the same units of measure (units of length, degree, time, &c.), be introduced into all countries? or is it sufficient to establish fixed rules for the reduction of the measurements used in different countries?

II. *Taking and calculation of the observations.*—18. Could corresponding times of observation be established at all meteorological stations. 19. According to what rules, periods of time, &c., are the mean values of the various meteorological observations to be calculated? Is it expedient to begin the meteorological year with the month of January, or with the month of December? 20. In what way, and for what periods of time are the normal values of the several meteorological elements to be deduced?

III. *Weather telegrams.*—21. Does the interchange of weather telegrams appear so useful that a wider circulation and more complete organisation should be given to it?

IV. *Maritime Meteorology.*—22. In what way would maritime meteorology be best introduced into the system of general meteorology?

V. *Organisation.*—23. Is it desirable that in each country one or more central stations for the superintendence, collection, and publication of meteorological observations, should be established? 24. In reference to the verification of instruments and the inspection of meteorological stations, can any adequate general rules be laid down? And is it advisable to introduce general instructions for taking and calculating meteorological observations? 25. In what way can the agreement of the standard instruments of the various central establishments be best secured?

VI. *Publication of Observations.*—26. Is it desirable and practicable to publish the meteorological observations of a limited number of stations in each country in a uniform manner and within a reasonably short time after the observations have been made? 27. How is the interchange of meteorological publications of various institutions and countries to be organised most simply, speedily, and certainly?

VII. *The Carrying Out of the Decisions of the Congress.*—28. What measures should be adopted for the accomplishment of the decisions and purposes of the Meteorological Congress? For this purpose, is the establishment of a permanent committee and the arrangement of further meteorological Congresses necessary?

BIRMINGHAM NATURAL HISTORY AND MICROSCOPICAL SOCIETY

ABOUT twenty members of this society, including several ladies, proceeded to Teignmouth in the beginning of September, in fulfilment of the proposed marine excursion, and took up their quarters according to agreement at the Queen's Hotel. The yacht *Ruby* had been chartered for the occasion, and proved a most seaworthy and serviceable craft. Dredging operations commenced on Monday, Sept. 1, and were continued daily throughout the week, in depths varying from $5\frac{1}{2}$ to 20 fathoms. The atmospheric, surface, and bottom temperatures were taken at each sounding, the maximum and minimum results being as follows :—

Atmospheric temperature,	Maximum		66°	Minimum	64°
Surface	,,	,,	,,	61°	,,	$58\frac{1}{2}$°
Bottom	,,	,,	,,	$60\frac{1}{2}$°	,,	58°

The averages were: atmospheric, $65\frac{1}{4}$°, surface, $59\frac{1}{2}$°, bottom, $58\frac{3}{4}$°. A Miller-Casella thermometer was used. On the whole the results of the dredging were very satisfactory. The weather was fine, but cloudy, with occasional rain, and sometimes a little too calm for the work. About 30 hauls of the dredge were made, and specimens of many of the marine invertebrate animals in the neighbourhood secured. The tangles attached to the bag of the dredge sometimes came up literally swarming with echinoderms. By far the most noteworthy capture was *Comatula rosacea*, the feather-star, two individuals of which were taken in the larval pedunculate condition attached near the base of a frond of *Laminaria*, which was torn off by the dredge.* The specimens measured about one-third of an inch each in length. Five young Comatulæ in a free condition, the largest about an inch across, were also taken. A subsequent haul on the following day brought up from the same locality three adults. The members of the Society had the unusually rare opportunity of seeing under the microscope the young feather-stars in the living state. They were but little thicker than sewing-silk, of graceful, erect, lily-like form, and very lively, bending and waving on the peduncle; the arms vigorously contracting in an inward direction. Drawings of the larval Comatulæ in the living state were made to scale by Mr. Wills, with the camera lucida, and the specimens mounted by him for exhibition to the Society. A full description will be communicated to the Society in a report of the excursion. During the evenings the members had the opportunity of examining under the microscope the pedicellariæ of the star-fishes and sea-urchins, and the whip and bird's head processes of certain of the polyzoa, also the structure of Botryllus and other tunicates, the larval forms of crustacea &c.; objects always interesting, but specially so to a society carrying on its work in an inland neighbourhood far removed from the sea. In the course of the week very enjoyable excursions were made by some of the members down the River Dart to Berry-Pomeroy Castle, Lustleigh, Becky Falls, Moreton Hampstead, Chagford, Exeter, Torquay, &c. On the whole, the excursion has proved a most successful experiment, quite fulfilling the expectations of those who projected it, and it is to be hoped may be succeeded by others in a wider field. The members received much kind attention from the Rev. R. Cresswell, Mr. W. G. Ormerod, Rev. R. C. Douglas, Mr. Adams, and other gentlemen. Most of the party returned to Birmingham by train on Monday, having had a most delightful excursion.—The members of the society who remained in Devonshire after the marine excursion had a great treat on the following Friday, when they were escorted through the famous cavern by W. Pengelly, F.R.S., who courteously explained to them the mode of conducting the explorations, the contents of the flora, and their relation to geological time. Mr. Pengelly also showed them at his own house the collection of bones, teeth, &c., of man, and the extinct bear, hyæna, dog, and other animals, and the flint implements of earlier and later manufacture found therewith in the cavern.

* They were taken in the vicinity of Torbay on Thursday, Sept. 5, at a depth of 12 fathoms on a limestone bottom, the bottom temperature registering 59°.

THE COMMON FROG

I.

WHAT is a Frog? At first, almost all persons will think, on meeting with this question, that they can answer it readily and easily. Second thoughts, however, will show to most that such is by no means the case.

Indeed many a man of education and culture will find himself entirely at a loss, if suddenly called upon for a reply to what is in fact a problem by no means easy of solution.

"The Frog is a small saltatory Reptile" will probably be the reply of the majority. But *is* it a Reptile? At any rate it begins life (in its Tadpole stage) like *a Fish!*

By the great Cuvier, however, as by very many naturalists since, it has been regarded as a Reptile and classed with Lizards, Crocodiles, and Serpents; and yet it may be a question whether the murine affinity connubially assigned to it in the Nursery tale, be not the lesser error of the two.

If the Frog was only known by certain fossil remains it would be considered one of the most anomalous of animals.

Many persons are accustomed to make much of the distinctive peculiarities of the human frame. In fact, however, Man's bodily structure is far less exceptional in the animal series, is far less peculiar and isolated than that which is common to Frogs and Toads.

The number and nature of both the closer and the more remote allies of the Frog; its distribution both as to space and as to time; its relationships whether of analogy or affinity * to very different animals; its bony frame-work; its muscles and nerves; its brain and sense-organs; its respiratory and excretory structures; its various changes from the egg to maturity, together with peculiarities of habit in allied forms; are all matters which will well repay a little attentive consideration.

Indeed it is probable that no other existing animal is more replete with scientific interest of the highest kind, than is the Frog.

About it are gathered biological † questions which bear upon the origin of species, and upon the course and mode of organic development, as well as other speculative problems to which answers are as yet far to seek.

If it is a fact that all the various species of animals have arisen through ordinary generation one from another by a process of development, the life history of the Frog may with reason be expected to have some bearing upon such a process, since every Frog begins its free existence with the organisation of a Fish, and after undergoing a remarkable "Metamorphosis," attains the condition of an air-breathing quadruped, capable of easy and rapid terrestrial locomotion.

There is a matter with respect to which the zoologist can hardly avoid regarding the botanist with envy. The creatures sought after by the latter may be rare or inhabitants of stations difficult of access, but at any rate they are incapable of flight or concealment, and specimens of some kind or other generally present themselves in plenty.

On the other hand not only does the townsman of a thickly-peopled land like our own, often meet with fewer animals in his country walks than he anticipated, but the explorer of tropical lands and virgin forests has frequently to endure disappointment from the contrast between the richness of a known local fauna and the little to be actually seen of the animal population of the place.

Frogs and Toads, however, are often enough seen both at home and abroad, and when perceived generally fall a far more ready prey to the collector than do the swift-running Lizards and small Beasts which are the commonest ground-animals met with besides. The group is also rich in species as well as in individuals, and it is spread over the far greater part of the habitable globe. Nevertheles Frogs and Toads have few admirers even amongst professed zoologists, and meet with no little neglect.

While the term "Ornithologist" ‡ is familiar to everyone, and the title "Erpetologist" § is so to all naturalists; the name "Batrachologist" ‖ has not yet been conferred on or assumed by any one worker in Science.

* Analogous relationship refers to the uses to which parts are put. Relationship of affinity refers either to such a relationship as that of kindred or to an ideal affinity reposing on similarities of structure.

† Biological questions are questions referring to living beings "Biology" being the science which treats of all living things, including both plants and animals.

‡ Ὄρνιθος, a bird, and λόγος, a discourse.

§ Ἑρπετόν, a reptile, and λογος.

‖ Βάτραχος, a frog, and λόγος.

Economically, Frogs are of little esteem in England save occasionally for bait and as the staple food of certain rare and interesting animals preserved in our menageries. Our American cousins indeed have given one more evidence of their French sympathies by the introduction of the Frog into their *cuisine*, and, as suits that land of the longest rivers and the largest lakes, it is no less a creature than the gigantic Bull-frog which figures in the *menu* of Transatlantic gourmets.

If zoologists and economists have neglected the Frog, the same assertion can by no means be made with respect to physiologists.

The Frog is the never-failing resource for the physiological experimenter. It would be long indeed to tell the sufferings of much-enduring frogs in the cause of Science! What Frogs can do without their heads? What their legs can do without their bodies? What their arms can do without either head or trunk? What is the effect of the removal of their brains? How they can manage without their eyes and without their ears? What effects result from all kinds of local irritations, from chokings, from poisonings, from mutilations the most varied? These are the questions again and again addressed to the little animal which perhaps more than any other deserves the title of "the Martyr of Science."

To return to our question at starting, "What is a Frog?"

To answer this, it will in the first place be well to make a certain preliminary acquaintance with the frog absolutely.

FIG. 1.—The Common Frog, *Rana temporaria.*

Secondly, to study those creatures which are most like it, and are, therefore, as we shall directly see, its "class fellows," living and fossil.

Thirdly, to investigate its anatomy so far as to be able to institute fruitful comparisons between its organisation and that of all other creatures belonging to the same great primary group of animals to which it pertains.

Fourthly, to sum up the results in a series of successively wider and wider comparisons, and by the light thence derived to answer as fully as the present state of Science allows the question first asked.

We shall then be able to answer that question, because we shall have ascertained how various parts of this creature form one organic whole as a system of mutually related structures; and how this whole and its parts are related to the entire series of animal existences from the monad up to man. Then, and then only shall we be able to say what a frog is.

In the first place it is necessary to acquire a general notion of the way in which animals are distinguished and segregated into groups, as well as the general system of arrangement of those groups and the mode of bestowing names which has been adopted by zoologists in common with botanists.

When we have acquired an adequate general notion of zoological classification we shall be able to see with what creatures the Frog is now admitted to be, in various degrees, allied.

The whole mass of animals of all kinds from man down to the lowest animalcula) is spoken of by the fanciful term *king-*

dom. Thus we have the animal kingdom in contrast with and in distinction from the vegetable and mineral kingdoms.

This great whole, the animal kingdom, is subdivided into seven great groups or *sub-kingdoms*, to one or other of which every animal known to us belongs.

Each of these sub-kingdoms (like every more subordinate zoological group) is characterised and defined by certain points of structure possessed by the animals which compose it and which serve to distinguish them.

Thus, if we take up an earthworm we see that its body is composed of a series of similar segments or rings placed one behind the other, and we know that it belongs to that great sub-kingdom of ringed animals termed *Annulosa*.

If we examine a thousand-legs or a wood-louse we see that here again the body is evidently composed of a series of rings or segments, to most of which jointed legs are attached. A successive survey of a lobster, a scorpion, a bee, a beetle, or a butterfly will reveal to us that all these creatures, however different in other respects, all belong to the same ringed type, *i.e.*, that they are all members of the sub-kingdom *Annulosa*, which

FIG. 2.—Tadpoles in different stages of development, from those just hatched (1) till the adult form is attained (8).

contains all such animals, all insects, together with spiders, earthworms, and leeches.

Another great sub-kingdom called *Mollusca* contains all snails, slugs, cuttle-fishes, and creatures of the oyster and scallop class. Such animals have not the body composed of a series of similar segments, but are united by characters less obvious indeed, but as distinctive.

A third sub-kingdom called *Molluscoida* is made up of the sea-squirts, or Ascidians (sometimes called Tunicates) and lamp-shells, together with minute animals living in water in compound aggregations, like the *Flustra* (or Sea-mat) so common on our coasts, the surface of which is pitted with minute depressions, in each of which a minute animal had in life its abode—as doves in a dove-cot, if we imagine each fastened in its cell by natural growth.

A fourth sub-kingdom, *Annuloida*, is composed of such animals as star-fishes and sea-urchins, together with internal parasites (tape-worms, &c.) and their allies.

The fifth sub-kingdom is named *Cœlenterata*, and contains all sea-anemones, jelly-fishes, Portuguese men-of-war, polyps, and coral animals, these being the little creatures which have formed the atolls (or coral islands) of southern seas, and the vast reefs which stretched for so many hundred miles on the earth's surface.

The sixth sub-kingdom, *Protozoa*, comprises the Sponges, the Infusoria, and all the lower forms of animal life.

Now the whole of these six sub-kingdoms may be contrasted with the last and seventh, which bears the name *Vertebrata*, from which they all differ in several important particulars, and therefore they are often spoken of by the common and convenient term *Invertebrata*.

When we examine a fish (such as a sole, a herring, or a mackerel), one of the first things likely to be noticed by us on dividing it, is a solid structure—the backbone—extending from the head to the tail, and coated externally by the flesh.

This backbone is soon seen to be made up of a number of pieces jointed together. Each piece is called in natural history a *vertebra*, and every animal in which such a structure is found, is called, on that account, a Vertebrate animal.

Now every kind of beast and reptile agrees with these fishes in the possession of the vertebrate backbone, as well as in a variety of other important characters, which constitute the definition of the sub-kingdom *Vertebrata*.

Thus in the development of the egg of every Vertebrata (such *e.g.* as in that of the fowl), the first indication of the future animal, is the appearance on part of its surface of a minute longitudinal furrow called the *primitive groove*. Next the margins of this groove ascend to meet together above, thus enclosing a canal, the lining of which becomes thickened and transformed into no less important a structure than the brain and spinal marrow.

Concomitantly with the development of this canal, there is found, immediately beneath it, a little gelatinous rod enclosed in a membranceous envelope, and called the *notochord*, or *chorda dorsalis*. It is this structure which is subsequently developed and becomes the backbone.

Another singular condition is invariably presented in the development of every vertebrate, whether the structures formed are transitory or permanent.

This condition is the appearance of a certain series of openings formed at the side of the neck, and which, in fishes, remain permanent as the gill openings. These openings are termed *visceral clefts*, and lead from the exterior into the throat. The solid pillars (or intervals) between the clefts are called *visceral arches*, and in creatures (*e.g.* fishes) which develop gills upon them, *branchial arches*.

In all vertebrates again (unlike insects or spiders) there are never more than four limbs, and these are supported by bones, or cartilages, which are clothed externally with flesh, and are not moved by muscles placed *within* the hard parts, as is the case with lobsters, insects, and all their allies.

The heart in all vertebrates, consists of at least two distinct cavities, and sends forth blood into a system of arteries, thence it is brought back again to the heart by other vessels termed the veins. On its way back to the heart, however, some of the veins carry blood to be redistributed in the liver, forming what is called the *portal* circulation.

In all the points above enumerated, the Frog (as we shall shortly see) fully agrees with beasts, birds, reptiles, and fishes, and thus shows that it differs from the immense majority of animals—the *Invertebrata*—and pertains unmistakeably to the seventh sub-kingdom of animals—the *Vertebrata*.

Now every sub-kingdom of animals is further divided into a greater or lesser number of subordinate (though still large) groups, termed *classes*. Each class is again subdivided into a certain number of smaller and more subordinate groups, each of which is termed an *order*. Each order is made up of *families*, each family being of course, smaller, and more subordinate than an order. Every family consists again of still more subordinate groups, each of which is termed a *genus*. And every genus comprises one or more *species*.

In zoology, every animal bears a name composed of two words. The first of these is a substantive, and denotes the genus to which any given animal belongs. The second word is an adjective—or a word used in an adjective sense—and denotes which species of the genus that given animal is. Thus the Chimpanzee is called *Troglodytes niger*, it is the species *Niger* of the genus *Troglodytes*, which genus contains also another species, namely, the Gorilla.

ST. GEORGE MIVART

(*To be continued.*)

NOTES

IT would be well if our men of science were to be found more frequently distributing prizes and taking an interest in the schools in which, thanks to the wisdom and energy of Mr. Cole, so many thousands of our people are learning science. In this Prof. Williamson has just set a good example by distributing the prizes at the Keightley School of Science and Art on Thursday last. Prof. Williamson, at the end of his speech, remarked that "We in this country give a peculiar position to Science in relation to material affairs. If we find a coal-seam we look upon it as wasteful not to work it and make the most of it, but what he said was, that to leave the clear heads and true hearts of our countrymen left useless was a greater waste, because he believed that they were infinitely more valuable than any coal-seam that ever was discovered."

AN anonymous donor has placed a large sum in the hands of the Committee of the Birmingham and Midland Institute, for the foundation of a Lectureship on the Laws of Health, and also for a prize fund in connection with the class. Dr. Corfield has been offered the post for this year, has accepted it, and will deliver an inaugural lecture in the Town Hall, Birmingham, on Thursday, October 9, at 8 P.M., on "Sanitary Progress." The course will begin on Tuesday, October 14, at 8 P.M., and be continued on succeeding Tuesdays until some time in April. It is intended more especially for the working classes, and both men and women will be admitted.

THE programme of the Birmingham and Midland Institute for Session 1873-4 is a very full one, and, to judge from what is set down, is well organised in its departments, and doing a thoroughly good educational work among all classes of the populous and important district in the midst of which it is established. At a merely nominal fee it places valuable scientific instruction within the reach of the poorest artisan.

SIR SAMUEL and Lady Baker left Alexandria for London on Tuesday.

WE would draw our readers' attention to a letter from Professor Thiselton Dyer, in this week's number, on the Oxford Fellowships in Science about to be competed for. We hope that, at any rate, the matter of Research will be taken into consideration.

NEXT year's meeting of the American Association for the Advancement of Science will be held at Hartford, Conn., and the officers elect are :—President, Dr. John L. Le Conte, of Philadelphia; Vice-President, Prof. C. S. Lyman, of New Haven; Gen. Sec., Dr. A. C. Hamlin, of Bangor; Treasurer, Mr. W. S. Vaux, of Philadelphia.

THE Italian Association for the Advancement of Science meets on the 20th inst.

THE business of the Social Science Congress opened at Norwich yesterday, with a meeting of the Council, after which there was a special service in the Cathedral; and in the evening the inaugural address was delivered by the President. To-day the exhibition of sanitary and educational apparatus and appliances at the Drill Hall, kindly lent for the occasion, will be opened with an address by the High Sheriff of Norwich. The address of the President of the Council, Mr. G. W. Hastings, will follow, after which the departments will meet in their respective rooms, and in the evening a *soirée* will be given by the local Executive Committee in St. Andrew's Hall. On Friday morning Mr. Joseph Brown, Q.C., will deliver his address as president of the Department of Jurisprudence and Amendment of the Law; and after the meetings of the various departments for the reading and discussion of papers, a working men's meeting in St. Andrew's Hall, at which the Mayor will preside, will conclude the business of the day. On Saturday an address on education will be delivered by Prof. W. B. Hodgson, LL.D., and after the rising of the departments the President of the Congress will distribute the certificates and prizes to the successful candidates at the last Cambridge middle-class examination. The address of Capt. Douglas Galton, C.B., F.R.S., president of the Health Department, will be given on Monday morning. The departments will meet as usual in their respective rooms, and in the evening a grand concert will be given in St. Andrew's Hall. Mr. Thomas Brassey, M.P., will deliver his address on Economy and Trade on Tuesday, and after the business of the departments a *soirée* will be given in St. Andrew's Hall by the Mayor, and the concluding meeting, preceded by a meeting of the Council, will be held on the Wednesday. In connection with the Congress there will be a conference on female education, and in the Exhibition short addresses will be delivered daily in the afternoon on the subject of the articles exhibited in the various classes. Excursions to various places, it is understood, are being arranged.

THE *Diana*, screw steamer, in which Mr. B. L. Smith left Dundee in May last on a voyage of discovery to the Polar Seas, by the Spitzbergen route, arrived in Dundee on Saturday last. The *Daily News* sums up the voyage of the *Diana* as follows:— A succession of gales was experienced—the weather on almost all occasions when the ship was in the open sea being such that, although she was provided with complete apparatus for sounding, deep-sea temperatures, &c, not nearly what was intended has been accomplished. Owing to the unfavourable nature of the ice, little in the way of exploration has been possible. The time had, however, been very fully occupied in dredging, trawling, photographing, surveying, and making as complete and perfect collections as circumstances permitted of the flora of Spitzbergen. Specimens of rare birds have been secured, and collections made, probably the first of any value. The collections of marine plants and animals are likely to prove especially interesting, and it has been discovered, among other things, that some parts of those seas hitherto reported as almost destitute of fish, abound in cod of excellent quality. In the way of geology everything possible was done in the parts unexplored by the Swedes, and numerous specimens of fossils have been brought back from the hitherto unvisited parts of the coast of the north-east land. From the appearance of open water seen in this expedition beyond Cape Platen, and also reported by the Swedes as existing—ascertained during their sleigh journey—it seems to be by no means certain that the route farther northwards which the *Diana* on leaving England hoped to reach does not exist, and the question still remains open, were it possible to reach this early in the season, whether a means of reaching a higher latitude to the north-east of Spitzbergen is not available. Mr. Smith has ascertained that the North Cape is situated on an island separated by a sound from the main land, and to this extent a knotty point has been determined. The expedition never got beyond 81°, while Mr. Smith in his expedition of 1871 got to 81·24°. He states that the *Diana* behaved admirably, but he did not realise his anticipations which would be achieved by the substitution of steam for sailing power.

WITH reference to our announcement of the forthcoming work by Mr. Boyd Dawkins on Cave Hunting,—the new line of inquiry which has added so much to our knowledge of ancient man,—we may now state the work will comprise the physical history of caves and their relation to the general physical geography of the district, as well as the history of their contents; and will treat of the men who have inhabited the caves of France, Spain, and Britain, during the historic, pre-historic, and pleistocene ages. The subject bristles with problems ethnological, archæological, and geographical, and demands a careful criticism that will sift the certain from the uncertain. The evidence will be given from which it may be concluded that the Eskimos lived as

far to the south as the Pyrenees in the palæolithic age, and that the Basque or Iberic population ranged as far north as the British Isles.

THE "Astronomical Observations taken during the years 1870—72, at the private observatory of Mr. Joseph Gurney Barclay, Leyton, Essex," by Mr. C. G. Talmage, contains well-arranged tables of double star observations, followed by copious notes on the observations, and occultations, and phenomena of Jupiter's satellites. Mr. Barclay thinks it so advisable to reduce and print observations at short intervals, that he has determined, wisely we think, to adopt the plan without waiting for a number to form a large volume.

AMONG Messrs. Smith, Elder and Co.'s announcements of forthcoming works, we observe the following:—A translation of Prof. "Hermann's Elements of Physiology," by Dr. Arthur Gamgee; and "A Text Book of Pathological Anatomy," by John Wyllie, M.D., Lecturer on General Pathology at the School of Medicine, Surgeons' Hall, Edinburgh.

AMONG Mr. Robert Hardwicke's autumn announcements we notice the following scientific books—"Man and Apes:" an Exposition of Structural Resemblances and Differences bearing upon questions of affinity and origin, by St. George Mivart, F.R.S. This work will be published simultaneously in America and England. "Waste Products and Undeveloped Substances:" a synopsis of progress during the last quarter of a century at home and abroad, by P. L. Simmonds, the editor of the "Journal of Applied Science." "Where there's a Will there's a Way; or, Science in the Cottage," by James Cash; being an account of the labours and lives of some north-country botanists in humble life. "The British Hepatica," with descriptions by Dr. Carrington, and drawings by J. E. Sowerby. This will be issued in twelve monthly parts. "Hooker's Synopsis Filicum," a new edition brought up to the present time by J. G. Baker, Royal Herbarium, Kew. "On Mounting Microscopic Objects," by Thomas Davies. A new edition, much enlarged, by John Matthews, M.D., F.R.M.S. This last-named work is nearly ready for publication.

THE library of the Manchester Athenæum was destroyed by fire on Sept. 24. The damage, estimated at 10,000*l.*, is said to be wholly covered by insurance.

WE have received the programme of the Edinburgh Veterinary College. We hope that, under the superintendence of the new Principal, Prof. Fearnley, this important institution will become more prosperous than it has ever been, and that the principles of the veterinary art will be taught in a thoroughly scientific way. That this is likely to be the case may be seen from the following list of professors:—Dr. Balfour, F.R.S., Dr. Murie, Mr. Dewar, F.R.S.E., Dr. Young, and Mr. Wally.

THE following are some of the most important additions to the Brighton Aquarium:—2 Octopus (*O. vulgaris*); 1 Group of Barnacles (*Lepas Hillii*); 30 Sea-horses (*Hippocampus ramulosus*); 5 African Crocodiles; 2 Alligator Terrapins (*Chelydra serpentina*); 1 Edible Turtle (*Chelonia midas*); 1 Sturgeon (*Acipenser sturio*).

THE additions to the Zoological Society's Gardens during the past week include a Brown Capuchin (*Cebus fatuellus*) from Guiana, and two Bonnet Monkeys (*Macacus radiatus*) from India, presented by Lord Louth; two Crested Ground Parakeets (*Calopsitta novæ-hollandiæ*) from Australia, presented by Miss L. E. Lyon, and two hatched; four Alpacas (*Lama pacos*), two Llamas (*Lama peruana*) from Peru, a Vicuna (*Lama vicugna*) from South America; a Cuvier's Gazelle (*Gazella cuvieri*) from Muscat; a Sultry Hermipode (*Ortyxelos meiffreni*) from West Africa; a Southern Mynah (*Acridotheres mahratensis*) from S. India, deposited; a Philantomba Antelope *Cephalophus maxwelli*) from Sierra Leone, received in exchange.

MOLECULAR EVOLUTION

AT quite uncertain times and places
  The atoms left their heavenly path,
And by fortuitous embraces
  Engendered all that being hath.

And though they seem to cling together
  And form "associations" here,
Yet, late or soon, they burst their tether,
  And through the depths of space career.

So we, who sat, oppressed with Science,
  As British Asses, wise and grave,
Are now transformed to fierce Red Lions,
  As round our prey we ramp and rave.

Thus by a swift metamorphōsis,
  Wisdom turns wit, and Science joke;
Nonsense is incense to our noses,
  For when Red Lions speak they smoke.

Hail, Nonsense! dry nurse of Red Lions,*
  From thee the wise their wisdom learn,
From thee they cull those truths of science
  Which into thee again they turn.

What combinations of ideas
  Nonsense alone can wisely form,
What sage has half the power that she has
  To take the towers of Truth by storm?

Yield, then, ye rules of rigid reason!
  Dissolve, thou too, too solid sense!
Melt into nonsense for a season,
  Then in some higher form condense.

Soon, ah! too soon, the chilly morning
  This flow of soul will crystallise,
And those who nonsense now are scorning
  May learn too late where wisdom lies.

$\frac{dp}{dt}$

THE BRITISH ASSOCIATION

WE are glad to say that the attendance at the Bradford Meeting was considerably larger than was at first stated. The total number of persons who attended the meeting is 1,983, and the total amount received, 2,102*l.*

The following is a list of the grants of money appropriated to scientific purposes by the General Committee:—

SECTIONAL PROCEEDINGS

SECTION A.—MATHEMATICS

Report of the Luminous Meteor Committee of the British Association on Observations of Shooting-stars in 1872-73.

Shooting-stars and large fireballs have appeared during the past year in more than usual varieties. Large meteors have presented themselves in considerable numbers, and ordinary shooting-stars in a more striking manner as regards the explanation of their origin than has often been the case in former years. Of all these kinds of shooting-stars, both large meteors and meteoric showers, much accurate information has reached the committee; but the extent of the knowledge acquired on all hands, has at the same time advanced so rapidly, that a smaller amount of attention has this year been directed towards the discussion of the individual descriptions, than the committee have hitherto bestowed upon them, and a more complete reduction of the separate observations will accordingly be attempted when the opportunities of the committee allow of their closer examination.

Those meteors, however, which have been observed simultaneously at more than one observing station have been selected from the collection for transcription in suitable columns in this report, and a list of large meteors is added, among which some have occurred that have without doubt been noticed, and may have attracted attention in other directions, than has hitherto come to the knowledge of the committee. Two of the largest fire-balls seen in Great Britain were aërolitic, or burst with the sound of a violent explosion on November 3 and February 3 last. The first passed over the central part of Scotland, and the second burst over Manchester and its neighbourhood at half-past five, and at 10 o'clock respectively on the evenings of those days. Aërolitic meteors and aërolites have also been noticed in the scientific journals of other countries, which have given rise to experiments on the composition of aërolitic substances, both chemical and microscopical, the conclusions of which continue to extend the range of our speculations regarding the origin of these bodies. Thus the existence of carbon and hydrogen in the atmosphere from which the largest iron meteorite yet found (a few years since upon the shores of Greenland) was expelled, confirms the discoveries of Grahame and Professor Mallet, in America, of the existence of the same gases in other meteoric irons. Dr. Wöhler has thus detected the oxides of carbon as gases in the vast meteoric iron of Ovifak found in Greenland, and brought to Stockholm during the last few years by Prof. Nordenskiöld, and the same gas was found by Prof. Laurence Smith in the siderite which fell recently in the United States. A connection between comets and meteorites appears to be indicated by these discoveries, in the spectra of some of which gases containing carbon appear to have been certainly recognised by Dr. Huggins.

The past year was distinguished by the occurrence of a most remarkable star shower on the night of November 27 last, to the expected appearance of which astronomers were looking forward with especial attention from the unexplained absence of the double comet of Biela (to which it belongs) from its accustomed returns in the last three of its periodical revolutions. The probability of the comet's path being marked by a meteoric stream into which the earth might plunge on or about Nov. 27 every year was already become a certainty, by the observation of such a meteoric stream on Nov. 30, 1867. On that night M. Zezioli of Bergamo, observed a distinct star-shower, according to Schiaparelli, no doubt of whose belonging to the missing comet could be entertained. Although the exact date of the shower could not be accurately foretold with certainty from the want of recent observations of the comet, yet every probability of its being seen was favourable to its reappearance last year, and those who awaited it, as well as many unexpected watchers of meteor-showers, were surprised by the brilliant spectacle which it suddenly presented. At the first approach of darkness on the evening of Wednesday the 27th of November last, the cloudy state of the sky unfortunately deprived observers in the south of England from witnessing the sight, but in Scotland, and north of the Midland Counties of England many uninterrupted views of it were obtained. On the European continent and in the United States of America, as well as in the East Indies, at the Mauritius and in Brazil observers were equally fortunate in recording its appearance, and few great star-showers have hitherto been more satisfactorily observed, or indeed more abundantly described. In an astronomical point of view the agreement of the time and other circumstances of its appearance with the supposed path of the lost comet is so exact as to prove that the calculations made by astronomers of that comet's orbit cannot be affected by any errors of a large sensible amount, and a proof almost certain is thus obtained that the disappearance of the comet is owing to no unexplained disturbances of its path; but that like some former comets of variable brightness, it has not improbably faded for a time out of view, and that at a future time a reasonable expectation may be entertained of re-discovering it pursuing its original path in repeated visits to the earth's neighbourhood, and to the field of telescopic observation.

Only partial views of the ordinary periodical meteor showers of December, January, and April last were obtained, of which some descriptions are contained in the Report.

Reductions of the scattered meteor-observations on ordinary nights of the year are an important subject of the Committee's inquiries, which have been kept in view in their operations of the past year. Captain Tupman having obligingly placed a list of nearly 6,000 such observations (made by himself) at their disposal, the greater part of which he has reduced to their most conspicuous radiant points, the present purpose of the Committee is most effectually obtained by the publication of the valuable meteor list which has thus unexpectedly come into their possession; and a graphic projection of the radiant points has been prepared, which will be printed as an illustration of the copious information that will be gathered by observers from the contents of Captain Tupman's list. The catalogue will be distributed this year to observers interested in the research; and to enable suitable lithographic charts to be added to it, it is hoped that the members of the British Association will assist the Committee with such liberal communications of their observations as they have hitherto abundantly supplied.

Note on a Natural Limit to the Sharpness of the Spectral Lines, by Lord Rayleigh, F.R.S.

In the explanation usually given of the broadening of the fixed lines with increased pressure, it appears to be assumed that their finite width depends on the disturbance produced by the mutual influence of the colliding molecules. I desire to point out that even if each individual molecule were allowed to execute its vibrations with perfect regularity, the resulting spectral line

would still have a finite width, in consequence of the motion of the molecules in the line of sight. If there is any truth at all in the kinetic theory of gases, the molecules of sodium, or whatever the substance may be, are moving in all directions indifferently, and with velocities whose magnitudes cluster about a certain mean. The law of distribution of velocities is probably the same as that with which we are familiar in the theory of errors, according to which the number of molecules affected with a given velocity increases, the nearer that velocity is to the mean.

By the principles of this theory of gases the mean square of the velocity of the molecules can be deduced from the known pressure and mass. If v denote the velocity whose square is equal to the mean, it is found that for air at the freezing-point, $v = 485$ metres per second.

At the temperature of flame, the velocity may be about three times greater. For the purposes of a rough estimate it will be accurate enough to take the mean velocity of the molecules at 1,500 metres per second, and that of light at 300,000,000 metres per second. The wave-length of the light emitted by a molecule moving with the mean velocity from the eye will therefore be greater by about five millionths than if the molecule were at rest. The double of this will be a moderate estimate of the width of the spectral line, as determined by the cause under consideration. We may conclude that however rare the gas, and however perfect our instrument may be, a fixed line cannot be reduced to within narrower limits than about a hundredth part of the interval between the sodium lines. I must leave it to spectroscopists more practised and skilful than myself to say whether this result is in agreement with the appearance of the spectrum.

SECTION B.—CHEMISTRY

The report of the Committee appointed to examine the *Methods of making Gold Assays and stating the Results thereof*, was read by Mr. W. C. Roberts.

The report stated that although the amount of alloy in gold could be ascertained to within a maximum error of 0·01 per cent., or one ten-thousandth part, yet there was an amount of difference between the results obtained by different assayers which required an explanation. The committee considered that the difference between different assayers was too great to be accounted for by the ordinary causes of error in analysis, and they had therefore come to the conclusion that the nominally assayed gold must have contained some impurity which had escaped the assaying process. The committee had precipitated eighty ounces of gold from no less than a hundred gallons of chloride of gold, and they suggested that the gold thus obtained might be used as a standard with which the gold assayed by different assayers might be compared.

Mr. A. Vernon Harcourt, F.R.S., and Mr. F. W. Fison, F.C.S., explained a *Continuous Process for Purifying Coal Gas and obtaining Sulphur and Ammonium Sulphate.*

Mr. Vernon Harcourt said that the usual method of freeing coal gas from sulphuretted hydrogen was by passing it through lime. But oxide of iron was also employed in place of the lime, the advantage possessed by the oxide being that whilst the lime, after it had served its purpose, was useless and difficult to get rid of, the oxide of iron could be used repeatedly for the same purpose. The chemical changes involved were, that when the gas had passed through the oxide the latter was changed into sulphide of iron; when the sulphide was exposed to the air, the sulphur separated and the oxide was re-formed, thus enabling the oxide to be again used. This was called a *continuous* process, because the oxide could be continuously used. But the process was not quite continuous, for after the oxide had been used some thirty times, it became so clogged with sulphur as to be useless. The advantage of the process he was about to describe was that the oxide could be used over and over *ad infinitum;* and, besides, the ammonia was secured in a marketable form. The present method of freeing gas from ammonia by "scrubbing," or passing it through a large receiver containing a small quantity of water spread over a large surface, had one or two defects. It did not secure the ammonia in a good form, and it probably diminished the illuminating power of the gas, for olefiant gas was soluble in water. The new process was applicable wherever oxide of iron could be used in the purifying process. The difference from the old process was that the oxide during revivification was moistened with a solution of ferric sulphate (per sulphate of iron), and a portion of the oxide was removed from time to time, and treated as follows:—It was first extracted with water by the use of a well-known arrangement. The soluble salts were sulphate of ammonia—formed in the purification by the reaction of ammonia upon ferric sulphate—and, in smaller quantities, sulphocyanide, hypo-sulphite, and probably sulphate of ammonia. This extract was mixed with a small excess of sulphuric acid; and yielded when concentrated by evaporation, crystals of ammonium sulphate. The remainder of the substance was then boiled with dilute sulphuric acid, which dissolved the oxide and left a residue of sulphur. The actual process of extraction by acid consisted in treating the substance successively with (1) a solution of ferric sulphate containing some free sulphuric acid; (2) with a more dilute solution of ferric sulphate to which sulphuric acid had been added; (3 and 4) with more dilute solutions of ferric sulphate—all these liquids being the product of a former extraction—and (5) with water. The liquid resulting from the first of the treatments enumerated above was a strong solution of ferric sulphate, which was used as already mentioned, by being mixed with the charge of oxide before it was replaced in the purifier. The residue of the final washing consisted almost entirely of sulphur, and required only to be dried. It would be evident that all the oxide which had been freed from sulphate of ammonia and sulphur by this treatment passed into the condition of ferric sulphate, and in this condition it was replaced in the purifier. There it again became oxide by the action upon it of the ammonia in the gas, which it completely removed, fixing it as sulphate. This system had been brought into use as a manufacturing process, and had been found to be, as far as could be judged, a complete success.

Mr. Fison explained at length the apparatus by which the process was carried into effect.

Mr. J. Spiller, F.C.S., gave a short communication on *Artificial Magnetite*, the object of which was, first, to point out an error in the statement of a chemical reaction occurring in several standard works of reference; and, in the second place, to indicate the formation of crystallised magnetic oxide of iron (magnetite) in the ordinary process of manufacturing aniline from nitro-benzol by the reducing action of metallic iron. Reference was made to "Reimann's Aniline and its Derivatives," and to Wagner's "Chemical Technology," where the action of iron upon nitrobenzol in the presence of acid (Béchamp's process) is stated to give ferric oxide, or a "hydrated oxide of iron." The author pointed to the fact that the ordinary residual product in this operation was *black*, and could be so far purified by washing and elutriation from the excess of iron, usually remaining in admixture, as to give a fine black pigment, which appeared under the microscope as minute octohedra, and was strongly magnetic. Chemical analysis showed this to consist almost entirely of magnetic oxide of iron, with such impurities as were inherent to the process, or previously existed in the cast iron. The physical properties of this form of oxide were further described, and its analogy to the native varieties of magnetic ore (Cornish and Dannemora) shown.

Mr. W. C. Roberts exhibited some specimens of artificial horn silver which he had formed by mixing strong solutions of silver nitrate and common salt.

Prof. Schafarick, of Prague, read a paper *On the Constitution of Silicates*, in which he developed his views as to the manner in which certain members of this class of bodies might be graphically represented.—Prof. Crum Brown, whilst complimenting the author on the importance of the step taken, pointed out that we should guard against confusing graphic formulæ, as applied to minerals, with those applied to organic substances, because they do not represent the same kind of knowledge. Structural formulæ in organic substances represented reactions, and not merely composition; in the case of minerals we had as yet no method of following their reactions.

Prof. Crum Brown then read a paper *On the Action of Sulphide of Methyl on Bromacetic Acid.* He said bromacetic acid dissolved readily in sulphide of methyl. The solution soon became warm and separated into two layers, the lower of which solidified into a white crystalline mass. The crystals were easily purified by washing with absolute alcohol, in which they were very sparingly soluble. Analysis had given a result for this compound which showed it to be a compound of one molecule of bromacetic acid, and one of sulphide of methyl. The compound was obviously analogous to hydrobromate of betain.

Mr. Jesse Lovett described an improved gas-burner.

simply a modification of Wallace's gas-burner. The improvement consisted in a simple mechanism whereby the air and gas could be shut off by one movement.

SECTION C.—GEOLOGY

Second Report on the Discovery of Fossils in certain remote parts of the North-western Highlands, by W. Jolly.

During the past year search has been made at various points along the great limestone strike of the North-western Highlands, but, with the exception of the Durness basin, from which the fossils already collected have been alone obtained, none have been found at any new locality. It is most desirable that continued search should be made for fossils, and to determine if the fossiliferous Durners limestone be the same as that in the line of strike from Eribol to Skye.

Report on Earthquakes in Scotland, by Dr. J. Bryce, F.G.S.

Last year a report on this subject was read at Brighton, stating that there had been but little to record during the year then reported on; but whilst the Association was sitting a shock occurred in the Comrie district, an account of which is given in the report now presented. The earthquake occurred on Aug. 8, 1872, at from 8m. to 10m. past 4 o'clock in the afternoon. The successive phases, according to almost all the observers, were :—a noise or sound, loud, heavy, and rumbling; a shock with a shaking and rattling of objects; and a wave-like motion of the ground. The undulations appear to have come from the W. or N.W.; according to some observers, from the opposite direction; but these probably did not distinguish between the first impulse and the recoil.

The extent of country through which the shock was felt is greater than that of any which has occurred since this inquiry was undertaken. The limits are marked by Stirling and Blair Logie on the S.E., and by St. Fillans on Loch Earn, and Glen Lednock on the N.W. The shock was feebler at their limits than in the country between, as about the Bridge of Allan, Dunblane, &c. The breadth of the disturbed area does not appear to have extended more than two or three miles from the Allan Water; the shock seems to have emanated near Comrie. The geological formations of the district are very various in character, and it does not appear that any connection can be traced between the nature of the rock forming the surface and the severity of the shock.

Another shock, which occurred at 9.55 P.M. on April 16, 1873, is briefly described. This was in the South of Scotland, in the parishes of Tyrone, Glencairn, and others adjacent. According to one observer, there was another shock in this district at 2.46 A.M. on the following morning.

Report of the Committee for Exploring the Settle Cave, by W. Boyd Dawkins, F.R.S.

This cave is of great interest, and is being explored by a local committee, aided by a grant from the British Association. In the newest layers there is evidence of human occupation during the historic period; but in the older cave earth, which contains the remains of extinct mammalia, no trace of man has yet been discovered. The exact age of the cave earth is a matter of dispute. Mr. Tiddeman, from the physical evidence alone, regards it as pre-glacial, or rather as older than the great ice-sheet of that district. Mr. Dawkins, whilst doubting the physical evidence afforded by the cave alone, is inclined to regard the fauna as pre-glacial, and he remarks:—"It is obvious that the hyænas, bears, mammoths, and other creatures found in the pleistocene stratum could not have occupied the district when it was covered by ice; and had they lived soon after the retreat of the ice-sheet, their remains would occur in the river-gravels, from which they are absent throughout a large area to the north of a line drawn between Chester and York, whilst they occur abundantly in the first glacial river deposits south of that line. On the other hand, they belong to a fauna, that overran Europe, and must have occupied this very region, before the glacial period. It may, therefore, reasonably be concluded that they occupied the cave in pre-glacial times, and that the stratum in which their remains lie buried, was protected from the grinding of the ice-sheet, which destroyed nearly all the surface accumulations in the river-valleys, by the walls and roof of rock, which has since, to a great extent, weathered away."

Report of the Boulder Committee, by Rev. H. W. Crosskey, F.G.S.

This committee was appointed at the Brighton meeting to collect and tabulate information upon the distribution of erratic blocks throughout England and Wales. Good work has already been done in Scotland by a committee formed for a similar purpose. It is evident that some steps should at once be taken to record the existence of remarkable blocks, and if possible to take some steps to ensure their preservation.

The report, which is necessarily chiefly preliminary, describes the distribution of boulders around Charnwood Forest, and refers to the existence of Charnwood Forest boulders in Shropshire. It also contains a notice, by Mr. Pengelly, of a large granite boulder below the raised beach in Barnstaple Bay. An account is given of the place adopted by the Geological Section of the Birmingham Natural History Society for mapping the boulders of their district, a plan so effective that we reproduce the paragraph referring to it in the hopes that other districts may follow the good example here set. "The Ordnance map of the neighbourhood of Birmingham has, in the first place, been divided by ruled lines with squares of one inch wide, each square enclosing a representation of one square mile of country. Enlarged maps, on the scale of six inches to the mile, were prepared from this. On these enlarged maps the boulders are to be marked by circles, the number of concentric circles representing the diameter of one boulder in feet. For collecting specimens of the rocks of which the boulders are composed, bags were made and numbered, corresponding to each square on the map. At the same time notes were to be made of any specimen that was of unusual interest. Finally it was proposed to represent, on a duplicate map, the number of boulders and the character of the rocks by discs of colour, so that a graphic representation of the boulders as to position, numbers, and kind of rock, would be given, and the source of any class of boulders, as granite *e.g.*, could be readily traced. It was further proposed to make a rough relief map of the district, so as to judge in what way the configuration of the country had affected the distribution of the boulders.

On the Whin Sill of Northumberland, by W. Topley, F.G.S., and G. A. Lebour, F.G.S.

This paper, the result of work by the authors during the progress of the Geological Survey, was laid before the section by permission of the Director-General of the Survey.

The basaltic rocks of the North of England occur in two forms, either as *dykes* cutting vertically through the rocks, or as *beds* lying amongst them. The intrusive character of the dykes is undisputed, but there is much uncertainty prevailing as to the character of the beds of basalt. The authors endeavoured to show that it too is intrusive, and has been forced in a melted state through the rocks long after their deposition and partial consolidation.

The Whin Sill is best known in Teesdale and along the face of the great Pennine escarpment. This district was only briefly alluded to, partly because it has already been often described, especially by Professors Sedgwick and Phillips, but also because the intrusive character of the rock is less evident there than in Northumberland.

An account of the literature of the subject was then given, and a MS. section of the Northumberland coast, made in 1822, by Sir Walter C. Trevelyan, Bart., was exhibited. Although the Whin Sill of more southern districts had been mentioned by earlier writers, it was not till the publication of Sir Walter Trevelyan's paper in the Wernerian Transactions for 1823, that attention was drawn to the intrusive character of the rock.

The Whin Sill is a true basalt, and does not differ in appearance or composition from the whin dykes of the district. In Teesdale it is very uniform in its position amongst the sedimentary strata; for this reason, and because it generally alters but slightly, if at all, the rocks above, Prof. Phillips, and most geologists who have given most attention to the Teesdale district, believe the whin to be of the same date as the beds amongst which it lies.

The object of the paper was to show that through Northumberland the Whin Sill is not so constant in position, that it frequently very greatly alters the beds above it as well as those below, and that, in numerous instances, it can be shown to cut through the strata in a manner that would be impossible with a contemporaneous bed. It also varies in position to an extent of more than 1000 feet, and often comes up, not in true beds, but in bosses.

Nothing can be certainly known as to the age of this Whin Sill. That it is later than the beds with which it is associated is

certain, but many considerations lead to the inference that it may not be later than the latter part of the carboniferous period.

SECTION D.—Biology.

Department of Anatomy and Physiology.

The Localisation of the Functions in the Brain, by Professor Ferrier.

All are agreed that it is with the brain that we feel, and think and will, but whether there are certain parts of the brain devoted to particular manifestations is a subject on which we have only imperfect speculations or data too insufficient for the formation of a scientific opinion. The general view is that the brain as a whole subserves mental operations, and that there are no parts specially devoted to any particular functions. This has been recently expressed by so high an authority as Professor Séquard. The idea rests chiefly on the numerous facts of disease with which we are acquainted. There are cases where extensive tracts of brain are destroyed by disease, or removed after a fracture, apparently with no result as regards the mind of the individual. Along with these facts we have others which are very curious, and which hardly seem to agree with this doctrine. One of these is that when a certain part of the brain is diseased, in Aphasia, the individual is unable to express himself in words. Other curious phenomena have been well described by Dr. Hughlings Jackson, viz., that certain tumours or pathological lesions in particular parts of the brain give rise, by the irritation which they keep up, to epileptiform convulsions of the whole of one side, or of the arm or leg or the muscles of the face; and from studying the way in which these convulsions show themselves he was able to localise very accurately the seat of the lesion.

The great difficulty in the study of the function of the brain has been in the want of a proper method. When we study the function of a nerve, we make our experiments in two ways. In the first place, we irritate the nerve by scratching or by electricity, or by chemical action, and observe the effect; and in the second place, we cut the nerve, and observe what is lost. In regard to the brain and nervous system, the method has been almost entirely, until recently, the method of section. It has been stated by physiologists that it is impossible to excite the brain into action by any stimulus that may be applied to it, even that of an electric current; they have, therefore, adopted the method of destroying parts of the brain. This method is liable to many fallacies. The brain is such a complex organ that to destroy one part is necessarily to destroy many other parts, and the phenomena are so complex that one cannot attribute their loss to the failure only of the parts which the physiologists have attempted to destroy.

About three years ago, two German physiologists, Fritsch and Hitzig, by passing galvanic currents through parts of the brains of dogs, obtained various movements of the limbs, such as adduction, flexion, and extension. They thus discovered an important method of research, but they did not pursue their experiments to the extent that they might have done, and perhaps did not exactly appreciate the significance of the facts at which they had arrived.

I was led to the experiments which I shall have to explain by the effects of epilepsy and of chorea, which have been explained to depend upon irritation of parts of the brain. I endeavoured to imitate the effects of disease on the lower animals, and determined to adopt the plan of stimulating the parts of the brain by electricity, after the manner described by Fritsch and Hitzig.

I operated on nearly a hundred animals of all classes—fish, frogs, fowls, pigeons, rats, guinea pigs, rabbits, cats, dogs, jackalls, and monkeys. The plan was to remove the skull, and keep the animal in a state of comparative insensibility by chloroform. So little was the operation felt that I have known a monkey, with one side of the skull removed, awake out of the state induced by the chloroform, and proceed to catch fleas or eat bread and butter. When the animal was exhausted I sometimes gave it a little refreshment, which it took in the midst of the experiments.

First, as to the experiments on cats, I found that on applying the electrode to a portion of the superior external convolution the animal lifted its shoulder and paw (on the opposite side to that stimulated) as if about to walk forward; stimulating other parts of the same convolution, it brought the paw suddenly back, or put out its foot as if to grasp something, or brought forward its hind leg as if about to walk, or held back its head as if astonished, or turned it on one side as if looking at something, according to the particular part stimulated. The actions produced by stimulating the various parts of the middle external convolution were a drawing up of the side of the face, a backward movement of the whiskers, a turning of the head, and a contraction of the pupil respectively. A similar treatment of the lower external convolution produced certain movements of the angles of the mouth; the animal opened the mouth widely, moved its tongue, and uttered loud cries, or mewed in a lively way, sometimes starting up and lashing its tail as if in a furious rage. The stimulation of one part of this convolution caused the animal to screw up its nostrils on the same side; and, curiously enough, it is that part which gives off a nerve to the nostril of the same side.

Results much of the same character were produced by the stimulation of the corresponding or homologous parts of the rat, the rabbit, and the monkey. Acting upon the anterior part of the ascending frontal convolution the monkey was made to put forward its hand as if about to grasp. Stimulation of other portions acted upon the biceps, and produced a flexing of the fore-arm, or upon the zygomatic muscles. The part that appeared to be connected with the opening of the mouth and the movement of the tongue was homologous with the part affected in man in cases of aphasia. Stimulation of the middle temporo-sphenoidal convolution produced no results; but the lower temporo-sphenoidal, when acted upon, caused the monkey to shut its nostrils. No result was obtained in connection with the occipital lobes.

These experiments have an important bearing upon the diagnosis in certain kinds of cerebral disease, and the exact localisation of the parts affected. I was able to produce epileptic convulsions of all kinds in the animals experimented upon, as well as phenomena resembling those of chorea or St. Vitus's dance. The experiments are also important anatomically, as indicating points of great significance in reference to the homology of the brain in lower animals and in man, and likewise served to explain some curious forms of expression common to man and the lower animals. The common tendency, when any strong exertion is made with the right hand, to retract the angle of the mouth and open the mouth on the same side, had been stated by Oken, in his *Natur-geschichte*, to be due to the homology between the upper limbs and the upper jaw; the true explanation being that the movements of the fist and of the mouth are in such close relation to each other that when one is made to act powerfully the impression diffuses itself to the neighbouring part of the brain and the two act together.

The experiments have likewise a physiological significance. There is reason to believe that when the different parts of the brain are stimulated, ideas are excited in the animals experimented upon, but it is difficult to say what the ideas are. There is, no doubt, a close relation between certain muscular movements and certain ideas which may prove capable of explanation. This is supported by the phenomena of epileptic insanity. The most important guide on the psychological aspect of the question is the disease known as Aphasia. The part of the brain which is the seat of the memory of words is that which governs the movements of the mouth and the tongue. In Aphasia the disease is generally on the left side of the brain, in the posterior part of the inferior frontal convolution, and it is generally associated with paralysis of the right hand, and the reason might be supposed to be that the part of the brain affected is nearly related to the part governing the movements of the right hand.

It is essential to remember that the movements of the mouth are governed bi-laterally from each hemisphere. The brain is symmetrical, and I hold it to be a mistake to suppose that the faculty of speech is localised on the left side of the brain. The reason why an individual loses his speech when the left side of the brain is diseased is simply this. Most persons are right-handed, and therefore left-brained, the left side of the brain governing the right side of the body. Men naturally seize a thing with the right hand, they naturally therefore use rather the left side of the brain than the right, and when there is disease, there the individual feels like one who has suddenly lost the use of his right arm.

I may, finally, briefly allude to the results of stimulating the different ganglia. Stimulation of the corpora striata causes the limbs to be flexed; the optic thalami produces no result: the corpora quadrigemina produce, when the anterior tubercles are acted upon, an intense dilatation of the pupil, and a tendency to draw back the head and extend the limbs as in opisthotonos;

while the stimulation of the posterior tubercles leads to the production of all kinds of noises. By stimulating the cerebellum various movements of the eye-balls are produced.

In the discussion which ensued Dr. Geo. Harley alluded to the effect of mental emotion on the bodily functions, and the possibility of producing disease by simply acting on the nervous system. Referring to phrenology, he said it was one thing to localise function in the interior of the brain, and quite another to specify functions by manipulating the external cranium; and he quoted a saying of Flourens with reference to phrenology: "Les hommes qui la pratiquent sont des charlatans, et les hommes qui la croient sont des imbeciles."

Dr. Carpenter remarked that the great work of the brain is done in the cortical substance, and in Dr. Ferrier's experiments the first effect of the stimulus is upon that particular substance, producing an intensification of the circulation through it; being in that respect different from the ordinary stimulation of a nerve which acts upon the fibrous substance of the medullary matter of the brain. He had long since expressed his disbelief in phrenology, which maintained that the animal functions were placed at the back of the head, and the intellectual at the front. Dr. Ferrier's experiments tended to show that the real seat of the intellectual functions was in the posterior part of the brain.

Dr. Brunton, however, alluded to the faculty of will and of self-restraint as distinguishing man from the lower animals, and said that this was probably situated in the *anterior* part of the brain. It was noticeable that criminals, who were deficient in that faculty, possessed only a small portion of brain in front of the head.

Prof. Burdon Sanderson said that the stimulus in Dr. Ferrier's experiments was, contrary to Dr. Carpenter's supposition, exactly like the ordinary excitation of a nerve, and that the effect was produced in an extremely short space of time.

Note on Huizinga's Experiments on Abiogenesis, by Dr. Burdon-Sanderson.

Under the title of a "Contribution to the Question of Abiogenesis," Prof. Huizinga has very recently published (Pflüger's Archiv. vol. vii. p. 549) a series of experiments which deserve notice as constituting a new and carefully worked out attempt to support the doctrine of spontaneous generation.

Prof. Huizinga begins his paper with the words *Multa renascentur quæ jam cecidere*, using them as an expression of the recurring nature of this question. He then proceeds to say that he was induced to undertake his inquiry by the publication of the well-known work of Dr. Bastian (whom he compliments as having awakened the exhausted interest of physiologists in the subject), his special object being to repeat the much-discussed turnip-cheese experiment.

Everyone knows what Dr. Bastian's observation is. It is simply this, viz. that if a glass flask is charged with a slightly alkaline infusion of turnip of sp. g. 1015, to which a trace of cheese has been added, and is then subjected to ebullition for ten minutes and closed hermetically while boiling, and finally kept at fermentation temperature, Bacteria develop in it in the course of a few days. This experiment has been repeated by Huizinga with great care, and the accuracy of Dr. Bastian's statement of fact confirmed by him in every particular; yet notwithstanding this he thinks the evidence afforded by these results in support of the doctrine so inadequate, that he, desiring to find such evidence, has thought it necessary to repeat the experiment under what he regards as conditions of greater exactitude.

Huizinga's objections to Bastian's experiment are two. First, that when a flask is boiled and closed hermetically in ebullition, its contents are almost entirely deprived of air, and (2) that cheese is a substance of mixed and uncertain composition. To obviate the first of these objections, he closes his flasks, after ten minutes boiling, not by hermetically sealing them, but by placing over the mouth of each, while in ebullition, a porous porcelain plate which has just been removed from the flame of a Bunsen's lamp. The hot porcelain plate is made to adhere to the edge or lip of the flask by a layer of asphalt with which the edge has been previously covered. The purpose of this arrangement is to allow air to enter the flask, at the same time that all germinal matter is excluded. It is not necessary to discuss whether this is so or not.

To obviate the second objection he alters the composition of the liquid used: he substitutes for cheese, peptone, and for turnip infusion, a solution containing in a litre of distilled water:—

Grape sugar	25	grammes
Potassium nitrate	2	,,
Magnesium sulphate	2	,,
Calcium phosphate	0·4	,,

The phosphate is prepared by precipitating a solution of calcium chloride with ordinary sodium phosphate, taking care that the chloride is in excess. The precipitate of neutral phosphate so obtained is washed and then added to the saline solution in the proportion given. On boiling it is converted into soluble acid phosphate, and insoluble basic salt, of which the latter is removed by infiltration. Consequently the proportion of phosphate in solution is less than that above indicated.

To the filtrate, peptone is added in the proportion of 0·4 per cent.

The peptone is obtained by digesting egg-albumen at the temperature of the body in artificial gastric juice made by adding the proper quantity of glycerin extract of pepsin to water acidulated with hydrochloric acid. The liquid so obtained is first rendered alkaline by the addition of liquor sodæ, then slightly acidulated with acetic acid and boiled. The syntonin thus precipitated is separated by infiltration from the clear liquid, which is then evaporated to a syrup and poured in a thin stream into strong alcohol, with constant agitation. The precipitated peptone is separated after some hours and washed with alcohol, and redissolved in a small quantity of water. The solution is again precipitated by pouring it into alcohol in the same way as before, and the precipitate washed and dried.

Flasks having been half filled with the liquid thus prepared (in 1,000, 2 each of nitre and Epsom salts, a trace of phosphate of lime, 25 parts of grape sugar, and 4 parts of peptone), each is boiled for ten minutes, closed while boiling, with the earthenware plate as above described, and placed as soon as it is cool in the warm chamber at 30° C. The experiment so made "gave, without any exception, a positive result in every case. After two or three days the fluid was crowded with actively moving Bacterium termo."

The readers of NATURE are aware that in June last I published a repetition of Dr. Bastian's experiments with a variation not of the liquid but of the mode of heating (see NATURE, vol. viii., p. 141). Instead of boiling the flasks for ten minutes over the open flame and closing them in ebullition, I boiled them, closed them hermetically, and then placed them in a digester in which they were subjected to ebullition under a pressure of two inches or more of mercury. The result was negative. There was no development of Bacteria.

Since the publication of my experiments Huizinga's have appeared. His result, regarded as a proof of spontaneous generation is clearly not superior to Bastian's. The substitution of a soluble immediate principle for an insoluble mixed product like cheese, and the use of a definite solution of sugar and salts are not material improvements. The question is not whether the germinal matter of Bacteria is present, but whether it is destroyed by the process of heating. Consequently what is necessary is not to alter the liquid but to make the conditions of the experiment as regards temperature as exact as possible. In this respect Huizinga's experiment is a confirmation of Bastian's and nothing more.

I have recently repeated it with the same modifications as regards temperature as those employed in my repetition of the turnip-cheese experiments. The result has been the same. In all other respects I have followed the method described by him in his paper.

I have prepared the solution of salts, grape sugar, and peptone in exact accordance with his directions. To obviate his objection as to the absence of air, I have introduced the liquid, not into flasks, but into strong glass tubes closed hermetically at each end and only half filled with liquid, the remainder of the tube containing air at the ordinary tension. Each of these tubes, after having been subjected to the temperature of ebullition under two inches of mercury for half an hour, has been kept since September 10 at the temperature of fermentation (32° C.). Up to the present time, no change whatever has taken place in the liquid.

As a control experiment I opened one of the tubes immediately after boiling, and introduced a drop of distilled water. It became opalescent in twenty-four hours.

In conclusion let me observe that I still maintain my resolution to take no side whatever in this controversy. I do not hold that spontaneous generation is impossible. I do not regard heterogenists as scientific heretics. All I say is, that up to the

present moment I am not aware of any proof that they are right.

On the Electrical Phenomena which accompany the Contractions of the leaf of Dionæa muscipula, by Dr. Burdon-Sanderson.

It is well known that in those structures in the higher animals which are endowed with the property of contracting when stimulated—viz., nerve and muscle—this property is associated with the existence of voltaic currents which have definite directions in the tissue. These currents have been the subject of very careful observation by physiologists. They require delicate instruments for their investigation, but the phenomena dependent on them admit of the application of the most exact measurements. The constant current which can be shown to exist in a muscle is called the normal current. The most important fact with reference to it is that it exists only so long as the muscle is alive, and that it ceases during the moment that the muscle is thrown into action. Other characteristics of the muscle currents were referred to, which we have not space to mention.

In certain plants said to possess the property of irritability, contraction of certain organs on irritation occur which strikingly suggest a correspondence of function between them and the motor organs of animals. Among the most remarkable are those of Drosera and some other plants belonging to the same natural order, particularly the well-known Venus' Flytrap (*Dionæa muscipula*). The Sensitive Plant, the Common Monkey Flower, the Rock Cistus, afford other examples.

Strange as it may seem the question whether these contractile movements are accompanied with the same electrical changes as those which occur in the contraction of muscle and in the functional excitation of nerve has never yet been investigated by vegetable physiologists. Mr. Darwin, who for many years has devoted much attention to the animal-like functions of Dionæa and Drosera, kindly furnished plants for the purpose of the necessary experiments, which have been made by Dr. Sanderson in the laboratory of University College, London. The result has been that the anticipations he had formed have been confirmed as to the existence of voltaic currents in these parts, and particularly in the leaf of Dionæa. By a most remarkable series of experiments (which will be published subsequently) made with the aid of Sir W. Thompson's galvanometer, he has shown that these currents are subject, in all respects in which they have been as yet investigated, to the same laws as those of muscle and nerve.

On Physiological Researches on the Nature of Cholera, by Dr. Brunton.

Without entering into the question of the nature of cholera poison, the writer regarded it as probable that its effects might be counteracted in the same way as those of other poisons—by appropriate antidotes. He supposed that if a poison could be found having a similar action to that of cholera, an antidote to the former might prove a remedy for the latter. The condition of cholera collapse has been attributed by Parkes and Johnson to contraction of the vessels in the lungs, and their theory is generally adopted. The writer fround that muscarin—an alkaloid derived from a species of poisonous mushroom—caused contraction of the vessels of the lungs and some of the symptoms which are counteracted by atropia. It therefore seems probable that atropia might be useful in cholera, and in fact an American practitioner has recently employed large doses of it with success. The fact that nitrate of amyl. which also relaxes the pulmonary vessels, is useless as a remedy in cholera, as well as the absence of distension of the right side of the heart in cholera patients during life, shows that Parkes and Johnson's theory is imperfect, and that one of the most important conditions in cholera is active dilatation of the large veins in the interior of the body. The condition might be relieved by digitalis. The effect of this poison was at once observed in cholera. The rice water stools in cholera were stated to have exactly the same composition as the fluid secreted after the division of the intestinal nerves in Moreau's experiment, and the profuse secretion from the intestines in cholera was therefore attributed to paralysis of some of the intestinal nerves. Injection of Epsom salts into the intestines also produced a profuse secretion, though this might be due to irritation and not to paralysis of the nerves. This is not lessened in the least by atropia, and it seems therefore probable that atropia will not prove a perfect remedy for cholera. Dr. Brunton is still endeavouring to find a remedy which will arrest this secretion.

On the Movements of the Glands of Drosera, by Alfred W. Bennett, F.L.S.

The peculiar movement of the glands which cover the margin and the upper side of the leaf of the Sundew has often attracted the attention of botanists. The observations were all made on the commonest species, *Drosera rotundifolia*.

It should be noted in the first place that the glands of Drosera are in no sense hairs, *i.e.* cellular expansions of the epidermis of the leaf. They have been shown by Groenland and Tiécul to be an integral part of the leaf itself, penetrated by a fibro-vascular bundle with spiral threads (in other words by a vein or nerve of the leaf) from one end to the other, and even furnished with stomata on their surface. They terminate in a pellucid knob within which is found their peculiar viscid secretion. Under a low magnifying power this secretion may be seen collected about the knobs, and stretching in thin glutinous strings from one to another. The secretion has probably an attraction for flies and other small insects, as, if the plant is examined in its native bogs scarcely a leaf will be found in which an insect is not imprisoned, and one leaf will very often show as many as three or four. The experiment was made of placing a very small insect, a species of Thrips, on a leaf at that time quite unencumbered beneath a low power of the microscope. Immediately on coming into contact with the viscid secretion it made vigorous efforts to escape, but these efforts only seemed to entangle it all the more deeply. The contact of the insect appeared to excite a stronger flow of the secretion, which soon enveloped the body of the animal in a dense almost transparent slime, firmly glueing down the wings, and rendering escape hopeless. It still, however, continued its struggles, a motion of the legs being still clearly perceptible after the lapse of three hours. During all this time the insect was sinking lower and lower down among the glands towards the surface of the leaf, but only a slight change had taken place in the position of the glands themselves, which had slightly converged so as to imprison it more completely. But after the struggles of the prisoner had ceased, a remarkable change took place in the leaf. Almost the whole of the glands on its surface and its margin, even those removed from the body of the insect by a distance of at least double its own length, began to bend over, and point the knobs at their extremities towards it, though it was not observed that this was accompanied by any increased flow of the secretion from them. The experiment was made in the evening; and by the next morning almost every gland of the leaf was pointing towards the object in the centre, forming a dense mass over it. The sides of the leaf had also slightly curved forwards so as to render the leaf itself more concave. The nearly allied Venus's Fly-trap, or *Dionæa muscipula* of the United States, which imprisons flies by a much more sudden motion of the sides of the leaf, collapsing when irritated on the upper surface, is said to digest and absolutely consume the insects thus entrapped. What becomes eventually of the prisoners of the sundew, my experiments have not been carried sufficiently far to ascertain. It will be seen that the most singular feature in the phenomena here described is that the motion of the greater number of the glands did not begin till after the insect had become comparatively motionless; and therefore it is very difficult to attribute it to the excitement caused by the struggles on any "contractile tissue" at the base of the glands, an explanation which has been offered for the sudden and rapid motions of the stamens of Berberis or the leaves of Mimosa. It is also quite certain that the impinging of raindrops on the surface of the leaf causes no similar motion, a peculiarity similar to that which Darwin has observed in the case of the motions of tendrils and of climbing stems. In order to determine what share in these motions of the glands was due to the organic nature of the substance imprisoned, and to its power of motion, the following experiments were also made:—A small piece of raw meat was placed on another leaf similar to the first. No immediate change was observable, and no increased flow of the secretion; but after the lapse of a few hours a perceptible inclination of the more distant glands towards the object took place. The next morning the piece of meat was found, like the fly, sunk down on to the surface of the leaf, with almost the whole of the glands converging towards it and above it in just the same manner. The changes here were therefore perfectly of the same kind as in the case of the fly, though apparently somewhat slower. After the lapse of twenty-four hours the piece of meat appeared decidedly lighter in colour; but an accident prevented the process of digestion being further traced. On other leaves

were placed a minute piece of wood and a small piece of worsted: and in neither of these cases was the least change perceptible after the lapse of a considerable time in the position of the object, nor in that of any of the glands, either those in contact with it or the more remote ones. It would appear, therefore, that the organised structure of the fly and of the piece of raw meat had some power of exciting this motion which is not possessed by matter of a different description.

SCIENTIFIC SERIALS

Poggendorff's Annalen der Physik und Chemie, No. 6, 1873.—This number commences with a paper by M. Seebeck, on the motion of sound in bent and branching tubes. He finds, among other things, that the gradual bending of a tube has little effect on the size of wave-length, but if a tube be suddenly bent to an angle, the sound-motion is considerably affected; it would seem that the motion of the air-particles did not suddenly alter in direction with the tube.—A series of experiments on the electromotive and thermo-electric forces of some metallic alloys, on contact with copper, is detailed by M. Sundell. The alloys examined were bismuth-tin, bismuth antimony (in various proportions), and German silver; the method employed in the case of electromotive force being that of Edlund, based on the fact, that a galvanic current, passing through an electromotor, produces in it, proportionally to its electromotive force, an absorption or production of heat, according as the current is in the same direction as that of the electromotor, or contrary to it. The alloys, like the pure metals, have the same order in electromotive as in thermo-electric series; and it appears that the proportion of thermo-electric to electromotive force is constant, and equal to that for the combinations iron-copper, and copper-bismuth. Comparative experiments on various pyrometric methods—air thermometer, expansion of solid bodies, calorimeter, dissociation of a compound, and electrical resistance, lead M. Weinhold to a preference for the last (or Siemens'), as the most reliable. The calorimeter, properly used, also gives good results.—M. Lorenz, of Copenhagen, furnishes a new determination of the electrical resistance of mercury, in absolute measure. He attributes the discordance in previous results to the employment of induced *currents*, of *variable* strength, and he adopts an ingenious method in which a *constant* electromotive force *without* current, is applied. The result of five experiments is 1 mercury unit $= 0 \cdot 9337$ Ohm's unit, or the mercury unit equal to $0 \cdot 9337 . 10^{10}$ absolute units.—Of the remaining papers we may note one by Kohlrausch on the electrochemical equivalent of silver, and mineralogical notes on wolfram, and on a new mineral, ardenite.

SOCIETIES AND ACADEMIES

London

Royal Horticultural Society.—General Meeting, Aug. 20.—W. A. Lindsay, Secretary, in the chair.—The Rev. M. J. Berkeley said Kerson's seedling gooseberry, a fine variety which gained a first-class certificate at the last meeting, turned out to be not a garden seedling but one originally taken from a common hedge in the neighbourhood of Peterborough. This was not a solitary instance of a fine variety of fruit being found in such places—the Bess Pool apple having been discovered in a plantation at Nottingham. Mr. Berkeley then alluded to a disease of the crocus very destructive to the gladiolus, and which also attacked the saffron crocus and the narcissus; it was first described by Montague under the name of *Tacon*. He concluded by remarking that vegetables treated with sewage were apt to be much deteriorated in flavour.

Sept. 3.—General Meeting.—Dr. Kellock in the chair.—Adverting again to the subject of *Tacon* in the Gladiolus, the Rev. M. J. Berkeley was inclined to attribute it to "sunstroke."—A bunch of grapes was exhibited from the parent plant of the Hampton Court vine; it dated from 1761.—A fungus (*Lentinus lepideus*) was sent by Sir Gilbert Scott, from the roof of a church at Croydon.

Paris

Academy of Sciences, Sept. 15.—M. Bertrand in the chair.—The following papers were read:—An answer to Father Tacchini's last note, by M. Faye. The author replied to the objections raised by the Italian observer to the cyclonic theory on the ground of the appearance of prominences where there are no spots. M. Faye considered that the pores, which are vertical cyclones, are the cause of the circulation of the solar hydrogen, and hence of the prominences. He also replied to some objections relating to the direction of the circular motion in cyclonic spots.—New researches on the analysis and the theory of the pulse in normal and abnormal states, by M. Bouillaud. The author announced the discovery of a secondary beat in the pulse, which he ascribed to a contraction and expansion of the arteries themselves.—On choleraic dejections as agents in the propagation of cholera, by M. Ch. Pellarin.—On the changes of form exhibited by Comet IV., 1873, by MM. Rayet and André.—On the movement of an elastic wire one end of which has a vibratory motion, by M. E. Mercardier.—On the products of the oxidation of meteoric irons and a comparison of them with the terrestrial magnetites, by M. Stan. Meunier.—Process for the preparation of a new aniline red, by M. E. Ferrière. The new colour is prepared by acting on acetate of aniline with ammoniacal cupric hydrate, and then saturating with sulphuric acid. On concentration ammoniac sulphate is deposited, and the colour remains. It is a purple red.

Sept. 22.—M. Bertrand in the chair.—On the chairman taking his seat, he at once proceeded to announce the deaths of M. Coste, of the Section of Anatomy and Zoology, and of M. Nelaton, of the Section of Medicine and Surgery; and to express in a few words the sorrow of the Academy at the grievous loss it had thus sustained. At the conclusion of the chairman's remarks. M. le Baron Larrey at once proposed that, to mark its sense of the double loss, the Academy should not hear any papers at the meeting, and that the correspondence only should appear in the *Comptes Rendus*. The following papers were accordingly printed:—Thermic researches on the condensation of gases by solids—continuation: absorption of hydrogen by platinum black, by M. P. A. Favre.—Certain observations on the winged form of the *Phylloxera vastatrix* in connection with the propagation of the insect, by M. Max. Cornu.—On the proper time for the application of the submersion treatment to vines tainted by Phylloxera, by M. L. Faucon.—On the proportion of carbonic anhydride in atmospheric air, and on its variation with the altitude, by M. P. Truchot. The author finds that the quantity of this gas diminishes as the altitude increases.—On coralline, by M. Commaille.—Note on a meteorite with a phosphorescent train seen on the night of September 28, 1873, by M. Chapelas.—The second part of M. Mercadier's note on the movement of an elastic wire, one end of which is endued with a vibratory motion.

FOREIGN ORDERS OF MERIT

IN a recent number of NATURE (vol. viii. p. 292) we intimated that honours had been conferred upon a large number of British men of science by the Emperor of Brazil and the King of Sweden. Some of the gentlemen to whom these Foreign Orders have been offered have, however, thought it right to refuse acceptance of them, mainly from loyalty to Her Majesty's stringent regulations respecting Foreign Orders, as issued by the Secretary of State for Foreign Affairs. A correspondent, who has himself refused to accept the Foreign Orders alluded to in our note, has favoured us with a copy of these regulations, and as many people are ignorant of their nature, or are even unaware that any such regulations exist, we shall be doing a service by giving them publicity in our columns. These "Regulations respecting Foreign Orders" are dated Foreign Office, May 10, 1855, and are as follows: —

"1. No subject of Her Majesty shall accept a Foreign Order from the Sovereign of any foreign country, or wear the Insignia thereof, without having previously obtained Her Majesty's permission to that effect, signified by a Warrant under her Royal Sign-Manual.

"2. Such permission shall not be granted to any subject of Her Majesty, unless the Foreign Order shall have been conferred in consequence of active and distinguished service before the enemy, either at sea or in the field; or unless he shall have been actually and entirely employed, beyond Her Majesty's dominions, in the service of the Foreign Sovereign by whom the Order is conferred.

"3. The intention of a Foreign Sovereign to confer upon a British subject the insignia of an Order must be notified to Her Majesty's Principal Secretary of State for Foreign Affairs, either through the British Minister accredited to the Court of such Foreign Sovereign, or through his Minister accredited at the Court of Her Majesty.

"4. If the service for which it is proposed to confer the Order has been performed during war, the notification required by the preceding clause must be made not later than two years after the exchange of the ratifications of a Treaty of Peace.

"If the service has been performed in time of peace, the notification must be made within two years after the date of such service.

"5. After such notification shall have been received, Her Majesty's Principal Secretary of State for Foreign Affairs shall, if the case comes within the conditions prescribed by the present regulations, and arises from naval or military services before the enemy, refer it to Her Majesty's Principal Secretary of State for the War Department, previously to taking Her Majesty's pleasure thereupon, in order to ascertain whether there be any objection to Her Majesty's permission being granted.

"A similar reference shall also be made to the Commander-in-Chief if the application relates to an officer in the Army, or to the Lords of the Admiralty if it relates to an officer in the Navy.

"6. When Her Majesty's principal Secretary of State for Foreign Affairs shall have taken the Queen's pleasure on any such application, and shall have obtained Her Majesty's permission for the person in whose favour it has been made to accept the Foreign Order, and wear the Insignia thereof, he shall signify the same to Her Majesty's Principal Secretary of State for the Home Department, in order that he may cause the warrant required by Clause 1 to be prepared for the Royal Sign-Manual.

"When such warrant shall have been signed by the Queen, a notification thereof shall be inserted in the *Gazette*, stating the service for which the Foreign Order has been conferred.

"7. The warrant signifying Her Majesty's permission may, at the request and at the expense of the person who has obtained it, be registered in the College of Arms.

"8. Every such warrant as aforesaid shall contain a clause providing that Her Majesty's licence and permission does not authorise the assumption of any style, appellation, rank, precedence, or privilege appertaining to a knight bachelor of Her Majesty's realms.

"9. When a British subject has received the Royal permission to accept a Foreign Order, he will at any future time be allowed to accept the decoration of a higher class of the same order, to which he may have become eligible by increase of rank in the Foreign Service, or in the service of his own country; or any other distinctive mark of honour strictly consequent upon the acceptance of the original Order, and common to every person upon whom such Order is conferred.

"10. The preceding clause shall not be taken to apply to decorations of the Guelphic Order, which were bestowed on British subjects by Her Majesty's predecessors King George IV. and King William IV., on whose heads the crowns of Great Britain and of Hanover were united.

"Decorations so bestowed cannot properly be considered as rewards granted by a Foreign Sovereign for services rendered according to the purport of Clause 2 of these Regulations. They must be rather considered as personal favours bestowed on British subjects by British Sovereigns, and as having no reference to services rendered to the Foreign Crown of Hanover."

Having given these Regulations, we may be permitted, perhaps, to make some remarks upon them. It will be seen that so far as scientific men, as such, are concerned, they are positively interdicted from accepting Orders offered to them by a foreign sovereign except in the improbable case of their doing scientific work for such a sovereign. On the face of them it is evident that they are the product of a time when it was thought that such rewards gained otherwise than on the field of battle might be open to suspicion. We can well understand that there may be reasons why diplomatists, projectors, and the like are better without such Orders, but these reasons do not apply to men of culture, whom a king might delight to honour for work done for mankind at large.

It is clear, therefore, either that the triumphs of Science and her followers were little known or were unappreciated when these Orders were issued, or that such possible recipients were purposely excluded. But are not the triumphs achieved by scientific men over the multitudinous forces of nature of infinitely more importance to humanity, and far more conducive to the highest glory of any country, than the greatest military triumphs that soldiers have ever achieved? Indeed, to what is it supposed that the dire art of war itself has reached its present state of comparative perfection, if not to the advantage which has been taken of the discoveries of Science? And does not the military superiority of one nation over another depend almost entirely on the thoroughness with which scientific theories have been applied to army organisation and the *matériel* of war?

It seems to us unjust and cruel that men of science, to whose labours it is mainly owing that our country and the world generally are mounting rapidly higher and higher in the scale of civilisation, should be practically debarred from accepting the few honours that come in

their way. Moreover, we should think that those who have the framing of these Regulations ought to be proud to think that our country produces so many men of science whom foreign sovereigns delight to honour, and instead of throwing obstructions in the way, should afford every reasonable facility to those who are thus honoured to accept and wear the Foreign Orders which may be offered to them. We cannot see that in any way their doing so would endanger the safety of the country nor be derogatory to the dignity and honour of our sovereign. May we not hope, then, that these Regulations as to Foreign Orders should not for ever remain as they are? They certainly permit one to infer that the only glory which those who promulgate them desire to see shed upon their country, is the barbarous glory which can be gained by a good fighter.

We shall be glad to receive the opinions of scientific men on this question.

LUBBOCK'S "MONOGRAPH OF THE COLLEMBOLA AND THYSANURA"

Monograph of the Collembola and Thysanura. By Sir John Lubbock, Bart., M.P., &c. Pp. 265. Seventy-eight plates. (Printed for the Ray Society: 1873.)

THE insects which constitute the Linnæan genus *Podura*, though small and apparently insignificant, present many interesting peculiarities of structure, and still more interesting characters bearing on the great problem of the true affinities and historical evolution of insects generally. They have, however, been comparatively neglected, and those who have worked at their classification have often done so in ignorance of each other's labours, so that the nomenclature of the group is confused. Sir John Lubbock has patiently investigated the characters of the British species, and compared them with those given by Gervais, Nicolet, Bourlet, and Tullberg. The genera he has been led to adopt are arranged in a tabular form on page 39. He gives good reasons for separating *Podura*, *Degeeria*, *Sminthurus*, and their allies from *Lepisma* and *Campodea*; and, while retaining Latreille's name Thysanura for the latter group, proposes for the remainder the new term "Collembola" (κόλλα, ἔμβολον), in allusion to the projection by which they attach themselves to foreign bodies. If this be adopted, there will be no title to designate all the insects belonging to Latreille's Thysanura; but though there is some inconvenience in restricting the meaning of a term already in use, the author would probably hold that the distinctions between the two orders are too great for them to retain with advantage a common name. The change would then be very much like what has been made in separating the herbivorous Cetacea of Cuvier from the rest, giving them a new name, and retaining the old one for the remainder. The relative affinities of either group to other Arthropoda are difficult to decide on. The absence of wings has long, and with ample reason, been discarded by entomologists as a character of importance in classification; the absence of tracheæ, though at first sight more important, does not apply to *Sminthurus* (not *Smynthurus*); the mouth is unlike either the mandibulate or the suctorial type; and the caudal appendage and ventral tube are too peculiar to be of service for comparison. On the whole, the author concludes that "if we represent the divisions of the Articulata like the branching of a tree, we must picture the Collembola and Thysanura as separate branches, though small ones, and much more closely connected with the Insecta than with the Crustacea and Arachnida."* After the chapters on the previous literature of Thysanura and their classification and affinities, comes what to many naturalists will be the most interesting part of the book, a discussion on the evolution of Insects, the origin of wings, and the light thrown on these questions by the study of the groups in hand. It would be impossible to do justice to this chapter in the limits of this article, and it is the less necessary since Sir John Lubbock has lately given our readers an exposition of his views on this subject in the series of papers lately published in these columns on the Metamorphosis of Insects. The remainder of the work consists of a general account of the anatomy of the Collembola and Thysanura, in which there are numerous exceedingly valuable original observations, and a systematic description of the characters, habitat, manners and customs of the various genera and species at present known, with copious synonymy. The value of the work is further enhanced by an appendix by Mr. Joseph Beck, on the Scales of Collembola and Thysanura, illustrated by twelve beautiful microscopic drawings, from the hand of the late Mr. Richard Beck. Thus the various points of interest offered by the groups treated of, to the microscopist, the entomologist, and the natural philosopher, are fully illustrated. Beside the figures, most of them coloured, many showing different stages of growth, which illustrate nearly fifty of the species described in the text, there are numerous careful outlines of anatomical details, which supply what is too often neglected by systematic naturalists. The tribute paid by the author to the artist whose intelligent skill has overcome the most grievous obstacles, will be endorsed by all who see these beautiful drawings.

We congratulate the Ray Society on the production of so excellent a work. This and the preceding volume by Prof. Allman on the Gymnoblastic Hydroids, will maintain its reputation, and we trust that a society to which we owe such works as Darwin's "Cirripedia," Parker's "Shouldergirdle," and Huxley's "Oceanic Hydrozoa," will continue to make so good a choice of books to publish, and will be still more widely supported than it is.

P. S.

* The relation of both to the Myriopoda is expressed in a sentence which some error of the press has rendered unintelligible. It would seem to make the Collembola, alone, a group of equal "value" with Myriopoda. We may remark here that there are an unusual number of misprints.

MONCKHOVEN'S "PHOTOGRAPHY"

Traité General de Photographie. Sixième Edition. Par Dr. v. Monckhoven. Avec figures dans le texte et trois planches photographiques. (Paris, 1873. Georges Masson, Libraire-Editeur, Place de l'Ecole de Médecine.)

THE great advance made by photography as an art, and the yearly increasing number of processes, have made it almost an impossibility for anyone [not professionally engaged as a photographer to keep abreast of the tide of improvement.

It is therefore with great pleasure that we welcome Dr. v. Monckhoven's "Traité Général," which seems to omit nothing in the way of recent additions to the number of photographic processes.

The Doctor commences his book with an historical notice of the origin of the art, in the course of which the irrepressible Egyptians make their appearance as having undoubtedly observed the effects of light on certain bodies; but, unfortunately, they have not handed their experience in the matter to posterity. The Egyptians and Greeks, however, having been disposed of, we have sixteen pages of really very useful historical matter, so arranged that a short paragraph is devoted to each of the more important processes, and which is rendered still more valuable by numerous references to the original papers of the various investigators to whom we owe the art.

The author then proceeds to give a sketch of the nature of light. Perhaps in a treatise of this sort one cannot expect a very comprehensive definition of such a subject. Still, however, something more satisfactory than the following might have been expected . . . . "il existe nécessairement entre le soleil et nous, un certain mode de communication dont nos yeux sont l'intermédiare; c'est ce mode de communication qui constitue ce que l'on appelle la *lumière*."

We then have a sketch of the chemical action of light, and a very good description of what a photographic laboratory ought to be, but, we fear, very rarely is. Considerable space is devoted to a description of the method of preparing the various substances required, including gun-cotton and collodion; and here we may observe that Dr. van Monckhoven makes use of the old system of chemical equivalents obsolete in England, and very nearly so on the Continent, a proceeding which is to be regretted in a work which is likely to remain for some time a standard book on its subject. We have noticed that photographers are singularly conservative on this point, for, to the best of our belief, there is not even now a photographic journal which makes use of the present atomic system of notation, a system which even nine years ago was largely used by chemists. A really admirable chapter on photographic optics succeeds that on photographic chemistry; one soon perceives how much the art has owed to the lenses constructed on the formulæ of Dallmeyer and Steinheil, and to the credit of English opticians we find that in the summary the lenses of the former are stated to surpass all others.

After dealing with cameras, printing frames, studios, and every other photographic requisite, the various processes are dealt with at length. Here we may note that specimens are given of two of the more recent mechanical printing processes, the "Woodburytype," and "Heliotype." Both are pigment methods, and so are not liable to the slow fading inevitable to the ordinary prints containing silver. Of them we can only say that while it is difficult to imagine that any process can surpass the former for artistic effect, the latter seems equally unsurpassable for any purpose requiring excessively minute and faithful reproduction of fine detail, such as is required in copying maps, prints, or diagrams.

A specimen of what is modestly termed the "retouche des clichés," is also given, but here we feel that we are treading on dangerous ground, as a portrait of a lady is the subject. Suffice it to say, that the general effect of this process seems to be like that of the elixir vitæ, and to make the happy patient young and handsome again.

We find considerable information also on photographic enamelling, and on the production of enlargements, where we observe that the heliostat and its use are described.

The work is illustrated with 280 woodcuts, executed in a style which is only found in foreign scientific works, and three specimen photographs are also given. In conclusion we must congratulate Dr. van Monckhoven on the production of so useful a book, hoping only that the chemical portion will be modernised and extended in future editions. Why do not some of our many amateur or professional photographers devote some attention to the chemical nature of their art? Of the rationale of many of the reactions we know absolutely nothing, and of the others our knowledge is not much greater. Such a research would not be of theoretical value only, but would materially aid in the attainment of that perfect application of means to ends by which alone the best results either in art or science can be obtained.

OUR BOOK SHELF

The Relations of the Air to the Clothes we wear, the Houses we live in, and the Soil we dwell on. Three popular lectures delivered before the Albert Society at Dresden. By Dr. Max von Pettenkofer, Professor of Hygiene at the University of Munich, &c. Abridged and translated by Augustus Hess, M.D., Member of the Royal College of Physicians, London, &c. (London: Trübner and Co., 1873.)

Dr. Hess has done well in translating these lectures by so great an authority on hygiene as Dr. Pettenkofer. Though the author does not believe that any knowledge of real value can be imparted by means of popular lectures, still they serve a good purpose in the way of "scientific edification and elevation, which are to raise our minds and hearts and to affect us like listening to good music." Though we in this country have perhaps less need to be instructed in the rules of hygiene than the mass of people on the Continent, still, it will be universally admitted that very few are acquainted with the principles which underlie healthy living, and still fewer can be at the trouble to put them into practice. In the little volume before us, which is well translated by Dr. Hess, the author expounds in an interesting and yet thoroughly scientific manner, the *rationale* of healthy living so far as our relations to the air are concerned, and shows the scientific principles on which we should choose our clothes both as to material and make, and which should guide us in building our houses. In the third lecture he speaks of the relations of the air to the soil, or on the Ground-air, and shows how much remains to be done before the principles of hygiene and their practical application can reach anything like perfection. The following extracts will give an idea of Dr. Pettenkofer's method of treatment :—

With regard to Clothing, the author says :—"When exposed to *luminous heat*, the *materials* of our clothing do not show very great differences, but in experimenting on shirtings of different *colours*, the following result was obtained :—When white absorbed 100, pale straw colour absorbed 102, dark yellow 140, light green 155, dark green 168, Turkish red 165, light blue 198, black 208. In the shade these differences nearly vanish. Krieger, in experimenting on tin cylinders filled with warm water, has found that a double tight covering by the same material does not retard the heat loss much more than a single one; but when the outer layer was

loose it retarded it very much. From this follows the practical truth, that we can produce a very different effect by the same number of clothes according to their make.

"Generally our clothing has been considered as an apparatus for keeping the air from us. This conception is utterly erroneous, and we can bear no garment which does not allow of a continual ventilation of our surface. Just those textures which are most permeable to the air keep us warmest. I have examined different materials for their permeability to air, and taking the permeability of air passing through flannel as 100, linen allowed 58, silk 40, buckskin 58, chamois 51, kid 1 part of air to pass through them. If the above-stated notion were correct, kid would keep us 100 times, chamois warmer by half, than flannel, and so on, while everyone knows, that it is quite the reverse."

With reference to Fur the author says:—"A fur is so arranged that its fine hair projecting into the air intercepts all the heat which flows from the surface of the body by radiation and conduction, and distributes this heat through the air which circulates between the single hair-cylinders. Thus the air, however cold it may be, reaches the nerves of our skin as a warmed air. Furred animals in winter, when touched superficially, give a very cold sensation; it is only near the skin that their hair feels warm. In a severe cold, certainly little of our animal heat comes as far as the points of the hair, from which it would escape by radiation or conduction, as the current of air in the fur cools the hair from its points towards its roots, and a severe cold penetrates only a little farther into the fur, without reaching the skin of the same. This can take place only at an exceedingly low temperature, or when a very cold air is in violent motion. In a well-furred animal the changes of temperature in the surrounding air only change the latitudes at the cold and warm zones in the fur; the place where the temperature of the body and the air equalise each other, moves between the roots and points of the hair, and for this reason a furred animal is not warmer in summer than in winter. In summer its heat leaves at the points, in winter near the roots of the hair."

Journal of the Proceedings and Annual Report of the Winchester and Hampshire Scientific and Literary Society, vol. i., part ii. 1871-2 (Winchester: Warren and Son, 1873).

WE are glad to see from the Third Annual Report of this Society that it continues prosperous, the number of members being, in 1872, 105. We hope good use will be made of the valuable herbarium of flowering plants, ferns, lichens, &c., collected and arranged by the late Mr. Hill, which has come into the possession of the society, through the generosity of the Mayor, Mr. R. P. Forder, and the President. The present part of the journal contains a number of papers, literary and scientific, read at various meetings of the society. The principal one is the Introductory Address delivered at the commencement of the third session, by the Rev. Canon Kingsley, on "Bio-Geology—the science which treats of the distribution of plants and animals over the globe, and the causes of that distribution." The address is an eloquent one, it can easily be imagined, shows extensive knowledge and great shrewdness, and contains many valuable hints both to young and old naturalists. Most of the other papers are also by clergymen, the principal ones being the following:—"On the Dawn of Thought in Greece," by the Rev. W. Awdry; "On the Metamorphosis of Lepidoptera," by Mr. J. Pamplin; "the Planet Jupiter," by the Rev. E. Firmstone, in which the author gives many interesting facts and speculations as to the condition of that planet; "Vesuvius previous to and during the Eruption of 1872," by the Rev. C. A. Johns, in which the author describes an ascent he made shortly before the last eruption, and appends a condensed abstract of Palmieri's account of the eruption. Appended to the journal is a valuable list of 315 works on the Geology, Mineralogy, and Palæontology of the Hampshire Basin, compiled by Mr. William Whitaker, of the Geological Survey.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

Wyville Thomson and the Ventriculidæ

I TRUST that you will afford me a little space for a few remarks upon some passages in Prof. Wyville-Thomson's book, the "Depths of the Sea," which, owing to many engagements, has only just come into my hands. So earnest a labourer in the wide field of truth will not, I hope, deem me discourteous if I point out one corner where his feet have slipped; and if it be objected that, after all, it is only in a small spot, the learned Professor will, I am sure, agree with the answer that, even in the smallest steps towards truth, attainable accuracy is important.

In 1847-48 my father published a series of papers in the "Annals and Magazine of Natural History," which were afterwards collected into a volume, on the "Ventriculidæ of the chalk, their microscopic structure, affinities, and classification." This work, which still remains, I believe, the authority on its subject, introduced order and classification where before all was confusion, expressly founding these upon two guiding principles of anatomy, the existence of which had been proved by searching tests. These two principles—the first being the structure, the second the fold, of the membrane—I am careful to recall, as I think there is considerable misapprehension regarding them. The chief locality of these fossils was in the south and west of England.

In his chapter on the Continuity of the Chalk, Prof. Thomson brings forward several families of ancient fauna as palæolontological evidence in support of his argument. Among these he devotes some attention to the Ventriculidæ (he calls them *Ventriculites*, but why? In the same sentence he uses the family name *Hexactinellidæ*); but, though he acknowledges my father's work, and refers to his "minute and most accurate description of their structure," it does not appear by what follows that he has quite comprehended it: "He (Mr. Toulmin Smith) found them to consist of tubes of extreme tenuity, delicately meshed, and having between them interspaces usually with very regular cubial or octohedral forms" ["Depths," &c., p. 482]. This description (the Professor will forgive me for saying so) does not convey a very clear idea of any structure, and certainly does not apply to the Ventriculidæ: if the word "tube" here means the body of the creature, it may in one sense be partially true of a few species in each of the genera—*Ventriculites*, *Cephalites*, and *Brachiolites*; but if it is intended to apply to the substance of the structure, I must say that it denotes a complete error. My father's words are, that "the membrane of the Ventriculidæ is composed of very delicate fibres," "the fibre is single and solid, never fistular," and that in this structure "*there are no tubes whatever*" (pp. 21, 25, 30). My father carefully describes this membrane, and marks it as the essential characteristic of the whole family of Ventriculidæ. Among the thirty-five species, for the most part marked by strong differences, he points out that *Ventriculites simplex* is the type of the whole family, consisting of a single membrane without a trace of fold.

Now, Prof. Thomson gives a figure of the octohedral structure to which I will not take exception, but he writes underneath it, "*Ventriculites simplex*, Toulmin Smith. Section of the outer wall, showing the structure of the silicious net-work." This implies, while citing my father's name (1) that this structure is proper to that species; and (2) that there is an inner wall. It also speaks of the net-work as silicious, while, two pages before, it is said, that "Mr. Toulmin Smith supposed that the skeleton of the Ventriculite had been originally calcareous." But though mistakes of this sort might easily arise through misapprehension, I must say I was very much astonished to see the figures, one of the entire fossil, the other of the "outer surface," given as "*Ventriculites simplex, Toulmin Smith*," from Mr. Sanderson's collection ("Depths," &c., pp. 483, 484.) A glance at Fig. 1, on the second plate in my father's book, will show that the name

has been misapplied to this specimen, which, as far as can be judged from the drawing, appears to be either *Ventriculites quincuncialis*, or one of the *Cephalites*, both quite different in outward appearance from the plain *simplex*. I know that it is often not so easy to distinguish the species of those preserved in flint as of those in chalk, but in this instance it is quite evident that it is not *simplex*.

My object in writing the above has been to vindicate my father's scientific accuracy, and to recall the facts he worked out. With regard to another point: it is stated by Prof. Thomson that some of the beautiful sponges discovered in the late deep-sea dredgings, especially the *Holtenia* and its allies, and the Ventriculites, "belong to the same family, in some cases to very nearly allied genera," or, as Dr. Carpenter puts it ("Good Words," October 1872, p. 703):—"Here we found the type of the old Ventriculites, which were supposed to be extinct, still living on in the deep sea." Much as my father would have delighted in the exquisite beauty of these new forms (the *Euplectella* he had examined in 1848), I do not think that he could have acknowledged the *Holtenia* as belonging to the ancient Ventriculidæ; nor, if the use of the word "type" depend for its force upon the character of structure, can it be truly said to be a type of that family. True, it possesses a silicious skeleton, but so does the Euplectella; and neither from Prof. Thomson's description ("Depths," pp. 70–72), nor my own examination, can I discover in the Holtenia any trace of or resemblance to the delicate structure and folded membrane of the Ventriculidæ. With great deference, therefore, to the opinion of these investigators (if I am wrong I will gladly learn), it appears to me that the modern type of the old Ventriculite is yet to be found.

I will add that the series of specimens figured in my father's book is in the British Museum, open to examination by students, together with a large portion of hi collection of the Ventriculidæ.

Highgate, Sept. 27 LUCY TOULMIN SMITH

"Deidamia"

I NOTICE in Prof. Wyville Thomson's extremely interesting papers the name *Deidamia* v. Willemoes-Suhm, used for a crustacean genus. This name must be changed, inasmuch as it is preoccupied in Articulata by Dr. Clemens in 1859. Dr. Clemens has used the title for a valid genus of North American Sphingidæ. I propose, therefore, for the genus in Crustacea, the name *Willemoesia*, in honour of its discoverer, with the two species *leptodactyla* and *crucifer*, the former the type.

AUG. R. GROTE,
Curator of Articulata, B.S.N.S.

Buffalo, U. S., Sept. 15.

Dr. Sanderson's Experiments and Archebiosis

IN a communication made to the British Association during its recent meeting at Bradford, Dr. Sanderson criticises the experiments of Prof. Huizinga, and also throws doubt upon the validity of the conclusions which I have drawn from experiments of my own. The "Note" appears in your columns this week; and seeing the nature of the conclusion drawn by Dr. Sanderson from his experiments, I am not a little surprised to find no mention in it of one most important point, viz., the temperature at which Bacteria are killed when immersed in fluids.

It must be obvious to all who understand the real nature of the question at issue, that no valid conclusion can be drawn by Dr. Sanderson from his experiments, unless he is able to argue from a definite conviction as to the temperature at which Bacteria are killed in fluids.

Now a study of Dr. Sanderson's writings would show the reader that up to the time of their publication he had every reason to believe that Bacteria were uniformly killed in fluids at a temperature of 100° C. If he still believes this to be true, he cannot (in the light of facts which he has learned concerning the productivity of previously boiled fluids in closed flasks) refuse his assent to my main proposition, viz., that Bacteria are capable of arising in fluids independently of living reproductive or germinal particles.

But the conclusion which Dr. Sanderson does draw from his experiments, and his imputation that facts do not warrant the conclusion of Prof. Huizinga and myself, would seem to imply that he is in possession of some new evidence subversive of his previous opinion, and tending to contradict views which I have recently published concerning the death-point of Bacteria in heated fluids. ("Proceedings of Royal Society," Nos. 143 and 145, 1873.)

As Dr. Sanderson is entirely silent upon this point, I venture to ask, both for my own information and for that of your readers, whether he still believes that Bacteria are killed by a temperature of 100° C. in fluids; and if not, upon what grounds he has changed his opinion?

In the face of his expressed intention (not a little contradicted, as I venture to think, by his public action) of taking no part in the "spontaneous generation" controversy, I ask Dr. Sanderson this question, because I cannot suppose that he would publicly throw doubt upon the validity of the conclusion which Prof. Huizinga and I have drawn from our experiments, in the absence of fresh evidence of his own upon the thermal death-point of Bacteria.

At present he has publicly expressed the opinion that we are not warranted in our conclusions, whilst he has given no sufficient information either to the world of science or to ourselves by which to test the correctness of his own conclusion. This seems neither just to us nor to himself.

University College, Oct. 3

Mr. D. Forbes's Criticism of Mr. R. Mallet's Volcanic Theory

AFTER the lapse of half a year Mr. D. Forbes has recurred in NATURE for Sept. 4, 1873, to my remarks published in NATURE of March 20 last, to his remarks upon my Theory of Volcanic Energy and Heat contained in his review of my translation of Palmieri's "Incendio Vesuviano," which appeared in NATURE of February 6 preceding.

I pray your permission to make some remarks upon Mr. Forbes's last production. They are the last by which I shall prolong this unpleasant controversy.

Mr. Forbes affirmed that if anything was certain, it was that the ejecta of volcanoes in all ages and all over the world are *identical* chemically or mineralogically, and upon this assumption passes a summary condemnation upon my theory, which he predicts will never receive acceptance from anyone—chemist, or mineralogist, or geologist. This rash and I will now say discourteous prediction I at once disposed of by giving the names of two authorities, whose competence even Mr. Forbes could not question, who had already accepted my views.

To this Mr. Forbes now says, that, as these gentlemen possessed for their guidance in assenting to the bare statement of my views, no better information than that upon which he dissented from them, so they may have been mistaken and not he. How is Mr. Forbes sure they had no better information, and can it be possible that he is so dull in weighing the force of evidence as to see no difference in probability of error between two assumed equally competent men—one of whom can assent to a proposition upon his prior knowledge and without waiting for proof; and another, who dissents, before he has heard what can be advanced in favour of the proposition and against his own previous knowledge or supposed knowledge? This, however, is now immaterial except as an indication of Mr. Forbes's capacity for weighing evidence.

To Mr. Forbes's grand objection I replied that it is based upon error as to fact—that it is not true that all volcanic solid ejecta are identical at all times and everywhere.

While I denied, and do again deny, that identity, chemical or mineralogical, exists in those bodies, I admitted that they do present a great general resemblance—which is just what we should expect.

I added a very important remark, namely that whether it were true or false that all volcanic ejecta were identical, chemically or mineralogically—the fact, whether one way or the other, did not apply to or affect my theoretic views as to the nature and origin of volcanic energy and heat; one way or the other, the identity or dissimilarity between the ejecta as found at the surface must be the same, whether they be derived from materials already and constantly in fusion, or be fused by elevation of temperature locally and temporarily produced; the materials fused being the same in both cases.

This last objection, which is fatal to Mr. Forbes's criticism, whether the foundation on which he has rested it be true or false, he either has not noticed or finds it convenient now to ignore.

I illustrated the want of identity, chemical or mineralogical, and yet the great general similarity at all times and places of

volcanic ejecta, by the analogy of the blast furnace, in which the same materials in the same proportions do not even in any one furnace, or at all times, produce identical slags.

What is Mr. Forbes's reply? That the *intention* of the iron master is to produce slags always the same, as the indication that the furnace is working well.

Doubtless the intention and desire of the iron-master is to produce good iron, and at all times as nearly as he can such a slag as indicates that he is doing so. But, as a matter of fact, he is not able to reach this. He can only approximate to constancy in the chemical or mineralogical constitution of his slags, which are never identical, even for short periods. Is this substitution of the intentions of the iron-master for the actual facts of the blast furnace slags, on Mr. Forbes's part, worthy of the candour of the searcher for truth; or does it not rather resemble the dialectic wriggle of the advocate?

Complete identity between any two rocky masses, ejected or otherwise, can only exist where the same elements in the same proportions are combined in the same way, and in the same molecular aggregation. If the mere presence in greater or less proportion in the mass, of certain crystallised minerals in any variable proportion, such as felspar, pyroxene, or leucite, in the magma of lavas, were enough to constitute identity, then nearly all the known rocks of the world, crystalline, igneous, and sedimentary, might be viewed as identical, for all consist of a few elements and of a few prevailing simpler minerals.

While still seeming to maintain his original statement, Mr. Forbes now substitutes for *identity*—a great *similarity* in all volcanic rocks. Further discussion is therefore needless—nor indeed would discussion of my views as to volcanic heat, &c., lead to any good result—with a gentleman whose notions of scientific method are such, that after six months' consideration he holds any distinction between hypothesis and theory to be mere hair-splitting, and whose notions of physico-mechanics are of that confused character, that he views pressure and work to be quite the same, and that it is matter of indifference whether we talk of "pressure converted into its equivalent, heat," or of work transformed into heat.

Would Mr. Forbes enlighten your readers by stating in figures what is the equivalent in heat, of the pressure of a weight of ten pounds, resting upon a rigid level plane?

Were Mr. Forbes of any real authority upon volcanic subjects, there might have been more ground for his sweeping and anticipatory condemnation of my views as to volcanic energy, which, however, in that case, he would never have uttered; but on looking down the list of his published papers, I do not find any treating of vulcanology simply, nor am I aware that he has ever enlarged the boundaries of our knowledge in that department by a hair's breadth.

Mr. Forbes appears to think that chemists, mineralogists, and geologists are the sole arbiters of all questions as to the nature and origin of volcanic heat and energy. Whatever they may have done to add to our knowledge of the visible and tangible phenomena of volcanic vents or cones, they have as yet contributed really nothing to discovering the nature and origin of volcanic heat itself, if we except some valuable negative evidence drawn from the gaseous emanations by chemists of late years, subversive of the older theories of the chemical origin of volcanic heat, still not quite extinct. It is much more to the physicist and theoretic mechanician dealing largely with the *physique du globe*, that we must look for further light, and whose province it will be to decide when the right key shall have been found to that enigma of ages, the true nature and origin of volcanic heat and energy.

I am done, sir, with this controversy, unwillingly entered upon, not in irritation, as Mr. Forbes states, but because I felt justified in protesting against new and I believe important views being obscured *in limine*, by objection based only on error.

My paper containing those views will ere long be before the world. My 100 separate copies (as author) from the "Phil. Trans." are already in the hands of or on the way to many men of science. The volume itself of the "Transactions" will no doubt appear before the end of the year, and to the verdict of the real men of science of the world, versed in the subject and competent to judge of it, I leave the result.

London, Oct. 6 ROBERT MALLET

On the Equilibrium of Temperature of a Gaseous Column subject to Gravity

FROM Mr. Clerk-Maxwell's reply to my note on this subject which appeared in your columns a short time since, it would appear that he does not profess so much fully to explain the difficulty suggested by me as to show that it is capable of explanation, referring your readers to his other works for further information. I would not, therefore, have troubled you further on the subject had it not occurred to me on reading Mr. Maxwell's letter that I could state the case in such a way as to render clearly apparent the grounds for taking different views on this point.

Let a vertical column of gas, subject to gravity and in a state of equilibrium as to pressure and temperature, be divided by a horizontal plane P into two parts, A above and B below.

In the time Δt let a mass M_1 of particles pass in their free course from A to B, and a mass M_2 from B to A.

Let the portion of A from which the particles composing M_1 proceed be called the upper stratum, and the corresponding part of B the lower stratum, then the following consequences may be deduced:—

1. From the equilibrium of density

$$M_1 = M_2$$

2. From the equilibrium of temperature the amounts of work in M_1 and M_2 while passing through P are equal.

3. From the effect of gravity the work in M while in A reckoning from the commencement of the free course of each particle composing M_1, is less than at P, while that in M_2 is greater.

4. Whence it follows that of the two equal masses M_1 and M_2 in the upper and lower strata respectively M_1 contains less work than M_2.

5. The work in M_1 while in the upper stratum reckoned as before, is the same as that of any other equal average mass in that stratum, and the same is the case also of M_2.

6. The average amounts of work in equal masses in the two strata, and the consequent temperatures of the strata are unequal, the lower stratum having the higher temperature.

I suppose Mr. Maxwell would deny the truth of statement (5). I presume he would argue as follows:—

"Of all the particles in the lower stratum which in the time Δt have at the commencement of their free course a velocity and direction such as would take them through P, gravity in selecting those which compose M_2 excludes those whose velocities are insufficient to overcome the effects of their weights, while in forming M_1 particles of low velocity are selected (included?), which, but for the effects of gravity, would not have cut P in their free courses, consequently the particles in M_1 have an average velocity less than that of the upper stratum from which they come, while the particles of M_2 have a greater average velocity than that of the lower stratum, and consequently the inequality of the average velocity of the particles in the two strata cannot be inferred from the inequality of the average velocities of the particles composing M_1 and M_2 while in those strata."

This argument, therefore, assumes the theory that in a given mass of uniform temperature there are particles moving with every velocity from nothing upwards to a certain limit, and mixed in certain proportions. That this is actually Mr. Maxwell's view I own I might have remembered, but I suppose I overlooked it from an impression in my own mind that the molecular motion was to be regarded as being of a planetary (or in the case of gases a cometary) nature. That in masses of the same temperature velocities were to be regarded as practically uniform, except in so far as affected by the distance of the particles apart, and that the so-called impacts of particles were more properly to be regarded as perihelion passages of bodies moving among each other in hyperbolic orbits. If this view is the more accurate one, then obviously the argument which I have assumed that Mr. Maxwell would use, falls to the ground.

Is there no possibility of testing the nature of the thermal equilibrium of a column of still air? The result would at any rate throw an unexpected light on the nature of molecular motion.

Graaff Reinet College, July 19 F. GUTHRIE

The Sphygmograph

DR. GALABIN, in his letter published in your last number, criticises my explanation of the cause of the small wave in the first part of the sphygmograph trace, which he calls the tidal wave. In his criticism he does not take into consideration the hæmodromograph traces of Chauveau, on which my explanation

is entirely based, and without a reasonable interpretation of which no explanation can be considered satisfactory. The hæmodromograph trace proves that the "tidal wave" of Dr. Galabin has a shock origin, as I have shown in the "Journal of Anatomy and Physiology" (Nov. 1872), and that the dicrotic wave is its resulting tidal wave.

Dr. Galabin appeals to the "tidal wave" in the trace from the artery at the foot, in proof of his explanation; I have taken many from that locality, and find that the tidal wave is never represented at all (as my explanation requires), for it is thrown so far back that it becomes blended with the primary rise.

My explanation of the details of the cardiograph is questioned, because my tracings are said to have been taken with "a lever moving on a pivot, and balanced between two springs." Such was undoubtedly the case in my cardio-sphygmograph observations, but not in my paper on the cardiograph trace, when the instrument employed was, what Dr. Galabin recommends, the ordinary sphygmograph, applied to the chest-wall.

As long as Dr. Galabin has not full faith in the reliability of the sphygmograph and its indications, it is almost impossible to maintain an argument with him, for it is hardly worth discussing points which may be only the results of instrumental imperfections. These are now understood, and can be easily eliminated.

A. H. GARROD

Venomous Caterpillars

THE caterpillars mentioned by R. Benson in your paper of August 14, are not at all uncommon in Calcutta. One day my little girl was brought to me with what appeared to be a good sized hairy caterpillar under her arm, and crying as if in pain, and on my trying to remove it in a hurried way, I discovered that it was nothing but a mass of small hairs. The child had put her arm into an empty tub on the inner edge of which the caterpillar was crawling. As soon as she pressed it, she started as if she had been stung. All the servants crowded round the child and pointed to their heads, but as I was not a proficient in their language I could not make out what they meant. I tried to do what I could with my fingers to remove the hairs, but this seemed very painful, and the swelling round about kept increasing. The ayah, however, soon appeared, attracted by the child's crying, and seemed to know what was to be done. She got some of my hair, made a kind of small brush of it, and gently passed it over the injured part. In a few moments the hairs were all removed, and nothing was left but a white blister. This remained for two or three days and then subsided. In the Calcutta schools the boys call these caterpillars "woolly bears," and if stung by them ask for "a head," and a few rubs soon removes the disagreeable appendages.

Calcutta, Sept. 9.

Harmonic Echoes

LORD RAYLEIGH's notes on Harmonic Echoes recall to my recollection a little experience which I had in hearing what I supposed to be overtones reflected.

I have frequent occasion to cross a portion of an open public park in which there are few trees. When any sharp sounds are heard in the neighbourhood, as, for instance, the sound of the rod in the beating of carpets in a field near at hand, curious responses to the blows of the rod are heard, and these responses or echoes have not the same pitch as the originating sound. I was puzzled for some time to account for this echo in an open park, with almost nothing above the level of the grass but the iron railings, till I satisfied myself, by occupying various positions, that the echoes were reflections of sound from these narrow fences. But why the difference in pitch between the originating sound and the echo? This, I concluded, *might* result from the overtones of the sound being reflected from the thin iron bars which constitute the railing. It was also observable that it was only the sharp sound emitted by the beating rod which was echoed, and not the dull sound arising from the carpet when struck. The hands struck sharply together will also cause an echo from the fences, which is higher in pitch than the sound of the clapping hands. It would be very interesting to experiment on this point by sounding, at a proper distance, notes of known pitch before narrow, upright, or horizontal bars, and then ascertaining the pitch of the echo, and the relation of the latter to the size of the reflecting surface.

W. J. M.

Glasgow

IT appears tolerably well established that harmonic echoes are selective echoes; that is to say, echoes which, from whatever cause, select and return one of the harmonies of the original without the fundamental.

It may perhaps be found that there are other selective echoes than the harmonic kind. In one of the galleries of the very large parish church of Monkstown, co. Dublin, the sound of S is heard with peculiar intensity, both in the singing and in the responses. This is not an echo, but it may perhaps be a fact of the same kind with selective echoes.

Old Forge, Dunmurry

JOSEPH JOHN MURPHY

Carbon Battery Plates

COULD you oblige me with information (or state where it could be obtained) respecting the process of manufacture of hard carbon battery plates, as I have some experiments on hand which necessitate the manufacture of plates of a peculiar shape, and I can neither get them made nor obtain sufficient information to enable me to make them well.

Warrington

T. W. FLETCHER

Brilliant Meteor

ON the evening of September 7, at about 9.7 P.M., while walking in a northerly direction in one of the streets of Tiverton, I saw a very large and brilliant meteor slowly descend from east to west, but in an almost vertical direction. The sky was almost entirely covered with a thin veil of cloud, which obscured the stars, so that I was not able to note its course with reference to them; but the altitude of the point at which it first appeared was about 45°, its path was inclined to the vertical at an angle of about 5°, and it disappeared behind a roof at an elevation of about 20°, at a point about 90° to the north of the moon which could be seen through the clouds. The light of the meteor was greenish and flickering, and far exceeded in intensity that of Venus when at her maximum brilliancy, but I could not see any train.

T. PERKINS

Reading School

NORTHERN LIMIT OF PHANEROGAMIC VEGETATION

CAPTAIN MARKHAM has most kindly presented to the Herbarium of the Royal Gardens, Kew, a small but very interesting collection of plants brought back by him from his recent Arctic voyage. Amongst them are four specimens which he obtained from Dr. Bessel, who collected them in lat. 82° N., the most northern position from which any phanerogamic vegetation has hitherto been procured. The locality appears to have been on the east side of Smith's Sound. The species are *Draba alpina*, L.; *Cerastium alpinum*, L.; *Taraxacum Dens-leonis*, Desf. var.; *Poa flexuosa*, Wahl.

JOS. D. HOOKER

THE WEALDEN BORING

THE readers of NATURE will be interested in learning that the lowest beds now reached by the Sussex boring are not Wealden, but of marine origin; that the most distinct of the shells yet examined by me is a Lingula, that it is *Lingula ovalis*, a shell of the Kimmeridge clay. The specimens which contain it were placed in my hands by Mr. Peyton, with Mr. Willett's consent. We are, in fact, already below the Wealden, in the pelagic sea-bed far from its ancient shore.

J. PHILLIPS

THE NEW MARINE ANIMAL FROM WASHINGTON TERRITORY

AT the meeting of the British Association in 1872, I exhibited before Section D specimens of some long white bodies resembling peeled willow-wands, which I had received from Barraud's Inlet, Washington Territory, with the information that they were the "backbones of a fish." Subsequently I published what intelligence I

could collect upon the subject in this journal,* and urged the expediency of further investigation in order to discover the true nature of these curious objects. I also called the attention of various correspondents in America to the same subject, and sent them copies of the article in NATURE.

It appears that the problem has now been satisfactorily solved, and that Prof. Kölliker, Mr. Mosely, and other naturalists, who held that these organisms were the axes of an unknown Alcyonarian polyp of the family Pennatulidæ were correct.

In a paper communicated to the Californian Academy of Sciences on the 18th of August last, of which I have received a separate copy, Mr. R. E. C. Stearns states that a specimen of the Polyp, of which these bodies are the axes, had been presented to the Academy by Dr. James Blake. Mr. Stearns describes the polyp at full length, and proposes to call it *Verrillia blakei.* He describes the general aspect of the species as resembling that of *Pavonaria quadrangularis*, but states that the polyps are arranged in "two unilateral longitudinal series."

I may add, that a communication from Dr. Edward L. Moss on the same subject, has been received by the Zoological Society of London, and will be read at one of the meetings next session. P. L. SCLATER

THE RAY SOCIETY†

THE Council, in presenting their thirtieth Annual Report, congratulate the members upon the continued prosperity of the Society.

The lapse of time, so marked by the production of a long series of volumes on zoology and botany, issued under the auspices of the Society, has scarcely lessened the original dimensions of the Printed List of Monographs in preparation and in progress; the completion of old memoirs being ever counterbalanced by offers of works from new authors. A recent proposal by Mr. G. B. Buckton to describe the British Aphides is a case in point. This addition will occupy the place left void by the publication of Sir John Lubbock's very valuable and interesting contribution to the study of insect life.

Since the last annual meeting some attempt has been made, not unsuccessfully, to reduce the arrears in the issue of the volumes. The monograph for the year 1871, the "Collembola and Thysanura," by Sir John Lubbock, Bart., M.P., has already been distributed to the members; the work for the year 1872, the "British Annelids," Part I., containing the Nemerteans, by Dr. W. C. McIntosh, has been so far finished that it will be ready in a few weeks' time for the binder; whilst the volume for the year 1873, the "Spongiadæ," vol. iii., by Dr. Bowerbank, is, with the exception of a single plate, completed.

The Council have considered that it would be to the advantage of the Society if members could obtain the past annual volumes at the original (or in some cases at less than the original) subscription price. With this view resolutions have been passed: first, that the annual volumes, or sets of annual volumes, issued during the last ten years should be purchasable by members at the subscription price of one guinea; and, secondly, that the books in stock, published earlier than the year 1863, should be supplied at a lower cost than that named in previous reports; and, thirdly, that certain of the volumes belonging to the years 1865, 1866, 1867, and 1868, formerly not distributed separately, should be offered to members for sums less than that of the year's subscription.

In accordance with these resolutions, a list of books and prices has been prepared. The volumes may be obtained on application to the secretary.

* See NATURE vol. vi. p. 436.
† Extracted from the Report.

The volumes in preparation for future years are:—

Mr. St. George Mivart's "Monograph of the Tailed Amphibia."

Rev. O. P. Cambridge's supplementary volume on "British Spiders."

Messrs. Douglas and Scott's work on the "British Hemiptera Homoptera."

Dr. Gaertner's work on "Hybridism in Plants" (Bastarderzeugung), translated from the German by W. Carruthers, F.R.S.

Prof. Haeckel's "Morphologie." A new edition, revised by himself, and translated from the German.

Mr. Hancock's Monograph of the "British Tunicata."

Mr. Andrew Murray's work on the "Coniferæ."

Rev. H. B. Tristram's "Synopsis of the Fauna and Flora of Palestine."

Prof. Westwood's Monograph of the "Mantidæ," with illustrations by Mr. E. A. Smith.

Mr. Buckton's Monograph on the "British Aphides."

The Council, in conclusion, would urge the members to assist in the work of obtaining new subscribers, seeing that very many old friends are being removed from the list of the Society year by year through death and various causes.

ON THE INTERNAL NOSE OF THE PECCARIES AND PIGS

IN examining the sections of the skulls of the Wild Boar the Babirussa, the Phacochoer, and the Peccary, I was struck with the great difference in the form and development of the internal part of the organ of smelling of the peccary as distinguished between it and the other genera.

The Wild Boar, Babirussa, and Phacochoer, have the nasal cavities on each side of the head large, broad, and continued from the outer to the internal nostrils in a simple manner, and they are only separated from the palate by a thin bone, as they are in the sheep and the generality of allied animals. In these animals the turbinal bone arises from the centre of the outside of each nasal cavity, and is divided above into two plates which are rolled backwards, towards the outer side of the nose. There is a perforation between the hinder edge of the intermaxillary bone and the palatine bone in front of the palate behind the cutting teeth which opens directly into the front of the nasal cavity just within the nostrils, as figured in Huxley's "Elementary Atlas," t. i. 4 *d.*

In the peccary the internal nostrils open into a small cavity, which soon becomes tubular, pervading a large hollow cellular part which occupies the space above the palatine bones, and then gives off a large opening on the outer side to the turbinal bones, and is continued in a smaller tube to a small opening on each side of the front part of the palate, behind the cutting tooth. This aperture is evidently analogous to the large perforation in front of the palate of the pigs, but is quite of a different structure. There is a cavity further in near the external nostrils, which forms an opening to the pituitary convolutions, to which I see nothing like in the skull of the pigs. The naso-turbinal is fixed by its upper edge to the upper part of the nasal cavity, and is rolled inwards, and there is a lamina on the lower side from the expanded part of the tubular internal nostril, which meets the one from the upper edge. The whole structure of this part is quite different from that in the pigs, and Phacochoer, and justifies the separation of the Peccaries as a different group from the pigs. I may also remark that in this genus there is a well-marked bony plate on each side of the brain cavity, that separates the edge of the cerebrum from the cerebellum. This septum is only slightly marked in the skull of the wild boar, and is entirely absent in the Babirussa and Phacochoer.

J. E. GRAY

ON THE SCIENCE OF WEIGHING AND MEASURING, AND THE STANDARDS OF WEIGHT AND MEASURE *

VI.

AT the time when the metric system was originated, the French standards of weights were the series known as the *Pile de Charlemagne*, the unit being the *Livre poids de marc* of 16 *onces*, and double the *poids de marc*. The metric equivalent of the *poid de marc* was subsequently determined to be 244·753 grammes. The *once* was divided into 8 *gros* (or drachms), and the *gros* into 72 *grains*. The old French *Livre* of 9216 French *grains* was therefore equal to 489·506 grammes, and 7554 English troy grains. The French *grain* was thus equal to 0·818 English troy grain. In determining the new unit of metric weight, it was necessary to ascertain the actual value in terms of the existing system of the *livre* and its subdivisions, of the provisional weights used; and from accurately comparing them with the old standards, it was deduced from the ascertained weight of the measured cylinder, that the weight of a cubic decimetre of distilled water at its maximum density, or at 4° C., which was 0·9992072 of the provisional kilogram, was equal to 18827·15 grains of the *poids de marc*. This, accordingly, was definitively adopted as the true weight of the kilogram, the new unit of metric weight.

The determination by the French Commission of the weight of a cubic decimetre of water at its maximum density differs somewhat from later authoritative determinations made in England and other countries, as may be seen from the following tabular statement:—

Date.	Country.	Observer.	Weight of cubic decimetre of distilled water at 4° C.
			Grammes.
1795	France	Lefevre-Gineau	1000·000
1797 & 1821	England	Shuckburgh and Kater	1000·480
1825	Sweden	Berzelius, Svanberg, and Akermann	1000·296
1830	Austria	Stampfer	999·653
1841	Russia	Kupffer	999·989
		Mean	1000·084

But the latest and most carefully executed determination by Kupffer agrees so closely with the French determination, that the actual weight of the primary kilogram may be taken as nearly identical with its theoretical definition, and sufficiently accurate for all practical purposes.

From the provisional brass kilogram, with its error thus ascertained by the French Commission, two new standard kilograms were constructed by Fortin, one of platinum, the other of brass, and each was determined, after numerous comparisons and the requisite corrections, to be of the true weight when weighed in a vacuum. The platinum weight was constituted the primary metric standard kilogram, and is known as the *Kilogramme des Archives*. Its form is that of a cylinder of about 39·4 millimetres in diameter, and 39·7 metres high, having its edges slightly rounded, being similar to that of the English platinum kilogram shown of the actual size in Fig. 12. The density of the *Kilogramme des Archives* has never been precisely determined, as it has been deemed hazardous to weigh it in water from a fear of its not being entirely free from the arsenic used in preparing the platinum, and of dissolving this arsenic, and thus diminishing the weight of the kilogram. Prof. Miller has assumed the volume of the *Kilogramme des Archives* when in its normal temperature of 0° C to be equal to the volume of 48·665 grammes of water at its maximum density, as determined by its cubic measurement, and consequently its density to be 20·5487. Other computations, however, differ slightly from this determination.

The brass kilogram was intended as the commercial standard, for regulating all ordinary metric weights in air, and was deposited at the Ministère de l'Intérieure Paris. One uniform shape is adopted in France for all brass kilograms. They are made in the form of a cylinder surmounted with a knob. The height of the cylinder is equal to its diameter, and the height and diameter of the knobs are equal to one half those of the cylinder. Like the platinum *Kilogramme des Archives*, the brass standard kilogram was never weighed in water, and its volume has been computed from its cubic measurement to be equal to that of 124·590 grammes of water at its maximum density, thus making its density 8·206. In our standard air, $t = 62°$ F. $b = 30$ in., the platinum standard kilogram will thus displace 59·25 milligrams of air, and the brass kilogram 151·75 mgr.; the apparent weight in air of the brass kilogram is consequently about 92 mgr. less than that of the platinum standard. This brass kilogram was assumed by the French Commission to be 88·5 mgr. lighter than the platinum standard, when weighed in ordinary air.

The primary platinum metre and kilogram were presented by the Commission on June 22, 1799 to the Corps Legislatif at Paris, and were legally constituted as the standards of length and weight of the new metric system throughout France by the law of Dec. 9, 1799. They were deposited at the Palais des Archives.

A platinum copy of each of the primary metric standards of the metre and kilogram was constructed at the same time, and deposited at the Paris Observatory. These standards, known as the *Mètre de l'Observatoire*, and the *Kilogramme de l'Observatoire*, were considered as next in authority to the primary standards.

The unit of capacity of the metric system, the *litre*, represents theoretically the measure of volume of a cubic decimetre, or the cubic contents of a metallic vessel of this capacity when at the temperature of melting ice. But practically, there is no material primary standard litre, and the legal measure of the litre is determined from the kilogram; that is to say, the litre actually is a measure containing a kilogram weight of distilled water at its maximum density. Such a measure can only be verified by computation, as the vessel itself must be taken at a different temperature from the water contained in it, the vessel at 0° C., the water at 4° C. Authoritative tables are therefore prepared for ascertaining the allowance to be made in every case for differences of temperature from the normal temperature, as well as for the difference of weight of air displaced by the metallic weight and the larger volume of water.

For metric measures of surface, the *are*, equal to 100 square metres in the unit; and for solid measures, more particularly for measuring wood, the *stere*, or cubic metre, is the unit.

The number and denominations of the metric weights and measures actually used in France and other countries, for which specific standards are provided, are as follows: they include the double and the half of each decimal unit, with a duplicate unit to make up the number 9 units:—

6 Metric Measures of Length . .
- Double metre
- Metre, divided into tenths or decimetres, &c.
- Half-metre, " "
- Double decimetre, divided into centimetres and millimetres
- Decimetre, " "
- (For land) Chain of double dekametre, or 20 metres, divided into metres, and links of 2 decimetres

* Continued from p. 389.

30 Metric Weights	20, 10, 5, 2, 1, 1 kilograms
	500, 200, 100, 100 grammes (hectograms)
	50, 20, 10, 10 „ (dekagrams)
	5, 2, 1, 1 „
	0·5, 0·2, 0·1, 0·1 gramme (decigrams)
	0·05, 0·02, 0·01, 0·01 „ (centigrams)
	0·005, 0·002, 0·001, 0·001 gramme (milligrams)

13 Metric Measures of Capacity	Hectolitre,	or	100	litres
	Demi-hectolitre,	„	50	„
	Double dekalitre,	„	20	„
	Dekalitre,	„	10	„
	Demi-dekalitre,	„	5	„
	Double litre,	„	2	„
	Litre,	„	1	litre
	Demi-litre,	„	0·5	„
	Double decilitre,	„	0·2	„
	Decilitre,	„	0·1	„
	Demi-decilitre,	„	0·05	„
	Double centilitre,	„	0·02	„
	Centilitre,	„	0·01	„

Total number of metric weights and measures used in France and other countries, 49.

For dry commodities, the demi-dekalitre is the smallest measure used. The litre being equal to a cubic decimetre, or 1,000 cubic centimetres, in volume, is also equal to 1,000 grammes weight of distilled water at its maximum density; consequently the

Demilitre	= 500 cubic centimetres, or grammes weight of water.		
Double decilitre	= 200	„	„
Decilitre	= 100	„	„
Demi-decilitre	= 50	„	„
Double centilitre	= 20	„	„
Centilitre	= 10	„	„

There are also graduated measures of 5, 2, and 1 cubic centimetres or grammes weight of water.

The earliest recognition by the British Parliament of the metric system thus established in France took place soon after the close of the war. On March 15, 1816, Mr. Davies brought forward a motion in the House of Commons, which was carried, for comparing the imperial standard yard with the French standard metre. The Government entrusted the necessary operations to the Royal Society, who obtained for the purpose two platinum metres from Paris. These had been verified by M. Arago, by comparison with the French standard. One was an end-standard, like the "Metre des Archives," but was nearly twice as thick, being 7·3 milimetres in thickness.

Fig. 11.—Decimetre and its nearly equivalent length of four inches

On one plane surface the word "METRE" is engraved, and on the other "FORTIN A PARIS," and "Royal Society, 44." This end-standard was determined to be exactly the length of a metre at the temperature of melting ice. The other was a line standard, the bar being nearly equal in width, but only 5·3 millimetres thick, and it is about 4 centimetres longer. On the upper surface is engraved "Royal Society, 45," and transverse lines, so fine as hardly to be seen with the naked eye, are cut about 2 centimetres from each end for defining the length of the metre, as shown in the following figure:—

The length of a metre is to be taken between the two transverse lines at the mid-width of the bar, and it has been determined to be less than a metre by 0·01759 millimetre, taken at the standard temperature of melting ice.

On being brought to this country, the two platinum metres were carefully compared by Captain Kater with the length of 39·4 inches on the Shuckburgh scale, considered by him to be the British scientific standard of length. Full details of the comparisons made with Captain Kater's microscopical comparing apparatus are given in Phil. Trans. 1818. It was required to determine the length of the platinum metre at its standard temperature of 32° Fahr. in terms of the brass standard yard of 36 inches at its standard temperature of 62° Fahr. Allowance was made for the different rates of expansion of the two metals, the co-efficient of expansion of the platinum being taken to be 0·00000476 for 1° Fahr., as determined by Borda, and that of brass 0·0000101, as found by Kater's experiments. The length of the metre at 32° Fahr. was thus determined from the *mètre à bouts* to be 39·37086 inches of the Shuckburgh scale at 62° Fahr., and from the *mètre à traits* 39·37081 inches, after allowing for its error = 0·00069 inch. The mean length of the metre was therefore 37·37084 inches of the Shuckburgh scale, and as this scale had been found 0·00005 inch longer than the Parliamentary standard, the true length of the metre was finally determined by Captain Kater to be 39·39079 British inches.

Ever since this period, this authoritative equivalent of the metre in imperial measure has been recognised as the true equivalent, and it received the sanction of Parliament, in the Act of 1864, for legalising contracts made in this country in terms of the metric system. It is, however, to be observed that it is the *scientific* equivalent of the metre in imperial measure. For all *commercial* purposes, on the other hand, the measure of a metre is always used at ordinary temperatures just as a yard measure is used, and the comparison of the two should therefore be more properly made at the same average temperature of 62° F. At such temperature a brass metre is equal to 39·382 inches, and this length is to be taken as the commercial equivalent of the metre in British measure. Of course, this difference of the equivalent in imperial measure of the metre at its legal and at its ordinary temperature, amounting only to $\frac{3}{1000}$ inch is perfectly immaterial in commercial measurements of small quantities, and the metre may safely be estimated as equal to $39\frac{3}{8}$ of our inches, and the decimetre at 3·94 inches, as shown in Fig. 11.

No satisfactory comparison of the primary kilogram with our unit of imperial weight was made until the year 1844, after the construction of the new imperial standard pound, under the authority of the Standards Commission. The comparison of the standard units of weight of the two countries was then undertaken by Prof. Miller, at the request of the Commission. He found that previous determinations of the weight of the kilogram varied amongst themselves from a minimum of 15432·295 gr. to a maximum of 15438·355 grains. Under these circumstances, he proceeded to Paris in the autumn of 1844, and obtained permission from the French Government to compare the Kilogramme des Archives with our English weights. For the comparison, he took with him the Par-

liamentary copies Nos. 1 and 2 of the standard pound, and two auxiliary platinum weights together, equal to about 1432·35 grains. The mean result of 60 comparisons was to find the Kilogramme des Archives epual to 15432·34813 grains. But Prof. Miller was not satisfied with this result, as one of the auxiliary weights was found to contain a small cavity filled with some hygroscopic substance, which rendered its weight slightly variable.

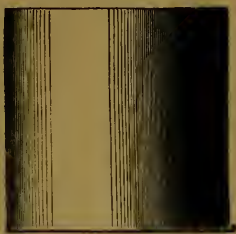

FIG. 12.—Platinum Kilogram 𝕮.

He therefore considered it requisite to make further comparisons directly with the English standard pound.

For this purpose, a platinum kilogram, constructed by Gambey, was procured at Paris by Prof. Miller, and was accurately compared by him with the Kilogramme des Archives. This platinum kilogram, designated as 𝕮 by Prof. Miller, is similar in form to the prototype, but is a little smaller, in consequence of the somewhat greater density of the platinum of which it is composed. Its

FIG. 13.—Gilt Gun-metal Kilogram 𝕽.

density was determined by hydrostatic weighings to be 21·13791. From the mean of 100 direct comparisons with the Kilogramme des Archives, 𝕮 was found to be lighter in a vacuum than the French standard by 1·56 mgr. (0·02412 gr.). For ascertaining the weight of 𝕮 in terms of the new imperial standard pound, Prof. Miller subsequently compared this kilogram with the imperial standard pound, together with each of its Parliamentary copies successively, and one of four auxiliary platinum weights, each of 1432·324 grains, constructed for the purpose, and accurately verified in terms of the imperial standard, by means of supplementary platinum weights. The mean result of 166 direct comparisons of 𝕮 was to find its value = 15432·32462 grains. The Kilogramme des Archives was consequently determined to be equal in a vacuum to 15432·34874 imperial grains, or 2·20462125 standard platinum lb. ; and the imperial standard pound equal to 453·5926525 metric grammes. These equivalents have since been generally accepted, and were legalised in this country by the Metric Act, 1864.

The platinum kilogram 𝕮 has since been deposited in the Standards Department, together with a second kilogram, of gilt gun metal, also made under Prof. Miller's directions, and intended as a standard for the adjustment of commercial metric weights, like the French *kilogramme laiton* deposited at the Ministère de l'Intérieure at Paris. This gilt gun metal kilogram was constructed by Oertling and has been denoted as 𝕽 by Prof. Miller. Its form is spherical with a knob. Its density is 8·3291°. The mean result of 24 comparisons with 𝕮 showed that in a vacuum the weight of 𝕽 was 1·47 mgr. less than 𝕮, and 3·04 mgr. less than the Kilogramme des Archives. In standard air ($t.$ = 18°·7 C., $b.$ = 755·64 mm.) 𝕽 displaced 143·92 mgr. and the Kilogramme des Archives 58·36 mgr. 𝕽 was then found to be 88·6 mgr. lighter in air than the French platinum prototype, and only 0·06 mgr. lighter than the French commercial brass standard kilogram.

Although the metric system was established in France as the legal system of weights and measures in 1799, it was not until more stringent provisions of law for enforcing its exclusive use were passed in 1837, that metric weights and measures began to be generally adopted in that country. Since that period it has been gradually adopted in other countries, and there is now every prospect of its finally becoming universally in use, and being acknowledged as an international system of weights and measures. Attention has been already drawn in NATURE, vol. vii. p. 197, to the proceedings of the International Metric Commission at Paris for the construction of uniform metric standards for all countries who have adopted or contemplated the adoption of the metric system, as well as to the material, an alloy of platinum and iridium, adopted for the new standards, and the peculiar form of the new International standard metre. It will therefore be sufficient here merely to show the adopted form of the new standard metres, as compared with that of the existing Standard Metre des Archives, in the following figures, all of the actual size :

FIG. 14.—Form of New Standard Metres.

The form of the new International kilogram will be the same as that of the Kilogramme des Archives, a cylinder of equal diameter and height, with the edges slightly rounded, as already described.

H. W. CHISHOLM

(*To be continued.*)

NOTES

A LETTER has been addressed by Dr. Anton Dohrn to the Colleges, and other bodies of the University of Oxford, giving an account of the cost, extent, and purposes of his zoological establishment at Naples, pointing out the incalculable advantages

furnished by the establishment to students of biology, and urging that at least one out of the many fellowships belonging to Oxford should be devoted to the purpose of affording a suitable man the opportunity of pursuing the practical study of biology at the Naples station. We have already printed the Report presented to the British Association by M. Dohrn, from which it will be seen that the University of Cambridge has hired a table; we believe the University of Oxford has refused to do so, and hence this appeal to the separate Colleges, by M. Dohrn. Let us hope that at least one of these bodies will come forward and maintain the credit of the University.

PROF. HENRICI's Introductory Address for the session at University College, delivered on Thursday last, dealt chiefly with the distinction between the results of Mathematical teaching in Germany and in England; that while in Germany almost every great mathematician (as an example the late Prof. Clebsch was pointed out) was the founder of a school, in England, on the contrary, no mathematical school had been founded in recent times. This the lecturer did not attribute to the paucity in this country of mathematicians of the very highest eminence,—indeed the names of Sylvester, Cayley, and Sir Wm. Thomson are alone sufficient to show that no country of Europe is ahead of England in this respect,—but rather to the want of personal influence exercised by them on younger minds, which has become almost impossible by the antiquated institutions of our old Universities. While the number of mathematical students at Cambridge exceeds that at a large number of German universities put together, the proportion of these students who are pursuing their studies for any higher purpose than that of taking a good degree—after which they allow them to be all but entirely neglected—is very small; and hence England is lamentably deficient in mathematical inquirers of the second and third class. Without wishing to see the German system introduced into this country in its entirety, Prof. Henrici pointed out some of the defects of our English system which he considered to conduce to this end; especially the encouragement given by the mode of examination to "cramming;" the small number of professorships; the fact that the remuneration of the professors is to a great extent dependent on the student's fees, and hence the comparatively high scale of charges; the slight encouragement given to the pursuit of pure science as a means of livelihood; and, above all, the want of that personal communication and interchange of ideas between teacher and pupil which tends so greatly to a promotion of the love of science.

A SPECIAL Meeting of the Council of the Society of Arts was held on Wednesday, Oct. 1, to consider the subject of National Museums and Galleries, and their bearing on public education. A Standing Committee was appointed for the purpose of bringing under Parliamentary responsibility the national museums and galleries, so as to extend their benefits to local museums, and to make them bear on public education. The following are the several objects in view for effecting this purpose:—1. All museums and galleries supported or subsidised by Parliament to be made conducive to the advancement of education and technical instruction to the fullest extent, and be made to extend their advantages to the promotion of original investigations and works in science and art. 2. To extend the benefits of national museums and galleries to local museums of science and art which may desire to be in connection, and to assist them with loans of objects. 3. To induce Parliament to grant sufficient funds to enable such objects to be systematically collected, especially in view of making such loans. 4. For carrying out these objects most efficiently, to cause all national museums and galleries to be placed under the authority of a minister of the Crown, being a member of the Cabinet, with direct responsibility to Parliament; thereby abolishing all unpaid and irresponsible trustees, except those who are trustees under bequests or deeds, who should continue to have the full powers of their trusts, but should not be charged with the expenditure of Parliamentary votes. 5. To enter into correspondence with all existing local museums and the numerous schools of science and art (including schools for music) now formed throughout the United Kingdom, and to publish suggestions for the establishment of local museums. 6. Also to cause the Public Libraries and Museums Act (18 and 19 Vict. c. lxx.) to be enlarged, in order to give local authorities increased powers of acting. We congratulate the Society of Arts on the step it has taken: we believe it is the most important piece of work it has ever set its hands to.

THE Council of the Society for the Promotion of Scientific Industry, looking to the enormous waste there is in the consumption of coal, whilst its cost is every day increasing, have resolved that an exhibition shall be held in Manchester of all appliances and apparatus, that tend to the economic use and saving of fuel, for the purpose of inducing attention to, and eliciting opinions of practical men on the matter, and of giving all consumers of coal an opportunity of comparing the various appliances, with a view to their adoption of that which will best serve their purpose. The exhibition will comprise:—1st. Appliances which may be adapted to existing furnaces, &c., whereby an actual saving is effected in the consumption of fuel. 2nd. Appliances which may be adapted to existing furnaces, &c., whereby waste heat is utilised. 3rd. New steam generators and furnaces, boilers and engines specially adapted for the saving of fuel and appliances, whereby waste products are utilised, and the radiation of heat prevented, &c., &c. The exhibition will include appliances used for manufacturing, agricultural, and domestic purposes. Either the apparatus itself, or diagrams, or models may be exhibited, and no limit is placed upon the class of articles to be exhibited. Exhibitors will be required to deliver their exhibits free of charge at the place of exhibition, and to remove them at the close of the exhibition; they must also erect them if necessary at their own expense. Every exhibit must be accompanied by a full description, which must include a statement of the particular work the apparatus is intended to perform. A duplicate of this statement must be handed in when application is made to exhibit. Exhibitors will be given every opportunity of explaining the speciality of their apparatus. All articles are exhibited at the risk of the exhibitor, though every reasonable care will be exercised. Further information may be obtained from the secretary of the society.

SIR SAMUEL AND LADY BAKER, with their nephew and some black servants, arrived at Paris on Monday morning, *en route* for London. The whole of them are in excellent health, and bear strong traces of exposure to an African sun. Interesting information concerning Sir Samuel's work in Africa, will be found in the *Daily News* of the 7th and 8th inst.

SIR HENRY RAWLINSON delivered the inaugural address on the commencement of the winter session of the Midland Institute at Birmingham on Monday evening. Referring to Arctic explorations, he said he indulged the hope that the year will not close before an assurance has been given that the *Challenger* Expedition will be supplemented by the despatch during next spring of a well-equipped Admiralty vessel which will be commissioned to endeavour to reach the Pole by pushing through Smith's Sound from Baffin's Bay in the track of the American ship, *Polaris*, whose fate has recently elicited so much sympathy throughout England.

SURGEON E. J. MILLIGAN, of the steamship *Africa*, writes from Sierra Leone, on the 12th ult., to the *Irish Times*, stating that on August 17, when returning from Loanda homeward, they steamed up the River Congo, and when at Banana one of

the passengers, M. Cressy, received a letter from a friend stationed 300 miles up the river. It contained the intelligence that about 200 miles farther in the interior a white man, accompanied by a number of native attendants, was proceeding in the direction of the West Coast. His supplies becoming short, he was prevented from proceeding by a tribe, and retained prisoner until some should be secured. From the description given by the native traders to M. Cressy's friend of this person, and also from the fact that no other white man is known to be in this region, it is generally inferred that it is Dr. Livingstone.

We regret to record the death of Sir Paul Edmund de Strzelecki (perhaps better known as Count de Strzelecki) who died on Monday morning at his residence in Savile Row, at the age of 77 years. Early in life he was a great traveller, and explored a great portion of Australia. He was elected a Fellow of the Royal Society in June, 1853, was a D.C.L., and a member of several of our learned societies.

Prof. Watson, of Ann Arbor, telegraphs to the Detroit *Tribune:* "On July 24 I observed a star of the twelfth magnitude, which, on Saturday night last (August 16), was missing from the place where first seen. A little to the west I saw a star of the eleventh magnitude, which proves to be the new planet (No. 133), and at present I suppose it to be that seen July 24."

The Fungus-show at the Royal Horticultural Society on Oct. 1st was a great success; never had there been a greater or better arranged display of these plants, classified under the two sections of "edible" and "poisonous." A new economical use for this class of plants was indicated by the Rev. Mr. Berkeley, who produced a cap made out of the beaten out interior mass of *Polyporus fomentarius*, the amadou or German tinder of commerce, which he described as both warm and light. It is stated that large use is made in Hungary of this material for caps and waistcoats, and it is also used for caulking boots.

One of the important and beautiful publications which characterise the Smithsonian Contributions to Knowledge is just issued under the title of "A Contribution to the History of the Freshwater Algæ of North America," by Horatio C. Wood, jun., M.D.

Now that so much attention is being paid to the introduction into our colonies of useful foreign trees and crops, we desire to call special attention to the publication at Brisbane of "The Olive and its Products: a treatise on the habits, cultivation, and propagation of the tree, and upon the manufacture of oil and other products therefrom," by L. A. Bernays, F.L.S., Vice-President of the Queensland Acclimatisation Society. The work has special reference to the advantages to be derived from the introduction of the olive into Queensland, and is printed and published at the expense of the Colonial Government.

News has been received to the date of May 1, from Mr. Henry Elliott, who has been engaged for two years past in making explorations and observations in the fur-seal islands in the Behring Sea. He announces the continued prosecution of his labours, the results of which were transmitted to the National Museum in the summer of 1872. He has especially devoted himself to an investigation of the habits of the fur-seal, walrus, and sea-lion, and has made a topographical survey of the rookeries upon a portion of the islands on which these animals come to bring forth their young. His work in 1872 was devoted mainly to St. Paul Island, but he expected, very soon after the date of his letter, to visit St. George and the other islands of the group, there to prosecute similar inquiries.

We consider it extremely creditable to the *Leeds Daily News* that it chronicles regularly and at considerable length the proceedings of the Leeds Naturalists' Field Club and Scientific Association, and we should like to see other provincial, and indeed metropolitan papers follow its example. The principal paper read at the Society's meetings during September was by Mr. James Abbott, on the structure and development of the Hepaticæ. The Society continues, we are glad to see, to investigate very thoroughly the natural history of the district.

We heartily endorse the following sentiment of the *Athenæum* in reference to the meeting of the British Association:—"The opinion is gradually forcing itself upon many of those who attend the meetings of the Association that some change in its method of procedure is becoming necessary. For the scientific men, on whom rests, more or less, the responsibility of keeping up the sectional business, either by doing official work or attending the meetings and taking part in the discussions, the labour is too exacting on an occasion which should have something of relaxation about it. Again, the tendency of the papers is necessarily to take a technical direction, which must put them beyond the range of the non-scientific audience. The sectional business is consequently unsatisfactory, both to those who take part in it and to those who attend as listeners. The Association should fulfil two functions—first, that of bringing together scattered scientific men, who otherwise rarely or never meet; secondly, of giving the general public some idea of what the scientific world is doing. For the first object, more leisure is required during the meetings—more opportunity of talking over amongst themselves the work which different men are occupied with. To attain the second object, instead of miscellaneous papers, short addresses, carefully prepared, might be delivered, with one or two invited speakers to follow. These addresses should be given at morning meetings, which might advantageously break up at one, leaving the afternoons free.

Messrs. Sampson Low, Marston, and Co. announce the following books to be published during the forthcoming season:—"The Heart of Africa; or, Three Years' Travels, Discoveries, and Adventures in the Unexplored Regions of the Centre of Africa," by Dr. George Schweinfurth. The district explored by Dr. Schweinfurth embraces the wide tract of country extending southward from the Meschera on the Bahr el Ghazal, and between the 10th and 3rd degrees of north latitude. The work will form two large octavo volumes, and will be illustrated by about 130 woodcuts from drawings made by the author during his journey.—"A Whaling Expedition to Baffin's Bay and the Gulf of Boothia. With an account of the rescue by his ship of the survivors of the crew of the *Polaris*," by Captain Markham, with maps and illustrations. The maps to this work will give the first authentic delineation of Hall's discoveries, and also contain several important corrections of the old charts.—"The Land of the White Elephant; or, Lights and Scenes in South-Eastern Asia," being a personal narrative of travel and adventure in Farther India, embracing the countries of Burma, Siam, Cambodia, and Cochin-China, by Frank Vincent, jun., with maps and plans.—"The Wild North Land," a winter journey with dogs across Northern North America, by Captain W. F. Butler, with a map; and a new work on Peru by Thos. J. Hutchinson, F.R.G.S., entitled, "Two Years in Peru, with Exploration of its Antiquities."

Messrs. Trübner's List of forthcoming books includes the following scientific works:—"From the Indus to the Tigris:" a narrative of a journey through the countries of Balochistan, Afghanistan, Khorassan, and Iran in 1872; together with a synoptical grammar and vocabulary of the Brahoe language, and a record of the meteorological observations and altitudes

on the march from the Indus to the Tigris, by H. W. Bellew, C.S.I., Surgeon to the Bengal Staff Corps. "The Rod in India;" being hints how to obtain sport, with remarks on the natural history of fish, otters, &c., and illustrations of fish and tackle, by H. S. Thomas, F.L.S., F.Z.S. A third and enlarged edition of the "Celt, the Roman, and the Saxon," a history of the early inhabitants of Britain, down to the conversion of the Anglo Saxons to Christianity, illustrated by the ancient remains brought to light by recent research, by Thomas Wright, M.A., F.S.A.

A DEPUTATION from the Trades' Guild of Learning waited on Tuesday afternoon on a Sub-Committee of the London School Board, at the invitation of the School-Management Committee, in order to urge upon the Board the adoption of systematic training in mechanics, &c., with the object of adapting the scientific instruction, provided or contemplated in the Board schools, to the future employments of the children. A memorial to the same effect has been presented to the Board, and is now under their consideration, in favour of the elementary teaching of applied science and art in the schools, in such a manner as to lay the foundation of a connected system of technical education.

NEWS has been received of the death at Quito, Ecuador, in June last, of Dr. William Jameson, an eminent naturalist, who resided for many years in Quito as a professor of chemistry and botany in the University. His contributions, both in zoology and botany, to public institutions in America and Europe have been very extensive.

DR. DAVID MOORE reprints from the "Proceedings of the Royal Irish Academy" a complete Muscology of Ireland, under the title "Synopsis of all the Mosses known to inhabit Ireland up to the present time."

THE additions to the Zoological Society's Gardens during the past week include two Black-headed Parrots (*Caïca melanocephala*) from Demerara, presented by Judge Lovesy; a Brown Bear (*Ursus arctos*), European, presented by Mr. M. B. Wilson; a Thicknee (*Oedicnemus crepitans*), British, presented by Mr. Patey; a Lesser Black-backed Gull (*Larus fuscus*), British, presented by Mr. C. W. Wood; a Hairy Armadillo (*Dasypus villosus*), from River Plate; a Burrowing Owl (*Pholeoptynx cunicularia*), from the same place, deposited; a Wattled Crane (*Grus carunculata*), from Africa, and two Bataleur Eagles (*Helotarsus ecaudatus*).

THE BRITISH ASSOCIATION

SECTIONAL PROCEEDINGS

SECTION A.—MATHEMATICS AND PHYSICS

On Etherial Friction, by Prof. Balfour Stewart, LL.D., F.R.S.

Professor J. C. Maxwell has made a series of experiments on the friction of gases. In these experiments a horizontal disc was made to oscillate in an imperfect vacuum near a similar disc at rest, and it was found that the motion of the oscillating disc was carried away by the residual gas of the vacuum at a rate depending on the chemical character of the gas, and depending also upon its temperature, but nevertheless independent of its density.

While the temperature of the arrangement remained constant, it was found by Prof. Maxwell that this fluid friction was rather greater for atmospheric air than for carbonic acid, while for hydrogen it was, I think, about half as great as for air.

On the other hand, when the temperature was made to vary the result was found to be proportional to the absolute temperature.

These experiments do not show that there is no such thing as etherial friction, that is to say, friction from something which fills all space, and is independent of air; but we may argue from them that such an etherial friction must either have been nearly insensible in these experiments, or it must, as well as the friction from the gas, have varied with the absolute temperature, in which case the two frictions would not be separated from one another by the method of the experiment.

Prof. Tait and myself have made some experiments upon the heating of a disc by rapid rotation in vacuo. In these experiments we found a mere surface heating due to air which varied not only with the quality, but also with the quantity of the residual gas; and we also found a surface effect (more deeply seated however than the former), which appeared to be a residual effect, and which it is possible may be due to etherial friction. We made no experiments at varying temperatures, but we made use of various residual gases, and we found that the heating effect for carbonic acid was perhaps a trifle less than for air, while that for hydrogen appeared to be about four times less than that for air. Now comparing Prof. Maxwell's experiments with ours, we have in the former a stoppage of motion which is rather less for carbonic acid than for air, and about half as large for hydrogen as for air. In the latter again we have a heating effect rather less for carbonic acid than for air, and only about one-fourth as large for hydrogen as for air. Thus it appears that the stopping effect of hydrogen in Prof Maxwell's experiments is relatively greater in comparison with air than is its heating effects in our experiments, when compared with that of air. The effects of these various gases would bear to one another more nearly the same proportion in both experiments, if we might suppose that in Prof. Maxwell's experiments there was mixed up with gaseous friction a very sensible etherial friction; but in that case it would be necessary to suppose that the etherial friction was proportional to the absolute temperature.

During the meeting of the British Association at Edinburgh, I brought before this section reasons for imagining that if we have a body in visible motion in an enclosure of constant temperature, the visible motion of the body will gradually be changed into heat. The nature of the argument was such as to render it probable (although not absolutely certain) that in such a case the rapidity of conversion will be greater the higher the temperature of the enclosure.

I will now refer to some experiments by Prof. Tait which formed the subject of the last Rede Lecture. These experiments were suggested to Prof. Tait by an hypothesis derived from the theory of the dissipation of energy which led him to think that the resistance of a substance to the conduction of electricity, and also of heat, would be found proportional to the absolute temperature. Mattiessen and Von Bose in the case of electricity, and Principal Forbes in the case of heat, had already proved that as a matter of fact the law was not very different from that imagined by Prof. Tait. The result of these experiments has been to confirm the truth of this law.

The following considerations also connected with the dissipation of energy point to the same conclusion. Perhaps we may regard the etherial medium as that medium whose office it is to degrade all directed motion, and ultimately convert it into universally diffused heat, and in virtue of which all the visible differential motion of the universe will ultimately be destroyed by some process analogous to friction.

Now in order to imagine the way in which either may possibly act in bringing about this result, let us imagine some familiar instance of directed motion, as for instance a railway train in motion. The train, let us suppose, and the air in it, are both in rapid motion, while the air outside is at rest. Now as the train proceeds, suppose that a series of cannons loaded with blank cartridges are fired towards the train. A series of violent sounds will go in at the one window, and out at the other of each carriage. Each sound will push some air from the stratum of air at rest into the carriage on the one side, and it will push some air from the carriage into the stratum at rest on the other side. Now in this operation it would seem that part of the visible motion of the train must be taken from it. To make another comparison, it is as if a series of individuals were jumping into the train at the one side, and out of it at the other, the result being that each carries away so much of the motion of the train, and therefore renders it difficult for the engine to drive the train. Each individual comes to the ground with an immense forward impetus, and rubs along the ground till this is lost; in fact, he carries with him so much motion of the train, and converts it into heat by friction against the ground.

Now something similar to this must happen to a substance in visible motion in an enclosure of constant temperature. The rays of light and heat will play very much the same part as the waves of sound, or as the crowd of people in the above illustration, at least if we except those which fall perpendicularly

upon the surface of the moving body. The moving body is like the train, and the rays of light and heat are similar to individuals entering the train from a stratum of ether at rest, and leaving the train into a stratum of ether at rest again, each probably transmuting into heat a certain small portion of the visible motion of the train as it were by a species of friction. Of course the intensity of such an influence would depend upon the intensity of the rays of light and heat. Now it matters not what the particular kind of motion be which constitutes this train—we may assert that all directed motion will suffer from such a cause, and possibly according to the same laws. Visible motion, such as that of a rotating disc, or of a meteor, is of course one form of such motion; but a current of electricity or of heat may equally represent some form of directed motion. In fine, we may perhaps suppose that all forms of directed motion are resisted by this peculiar influence, which evidently depends upon what we may term the temperature of the ether, or at least upon the intensity of those vibrations which the ether transmits.

On a Periodicity of Cyclones and Rainfall in connection with the Sunspot Periodicity, by Charles Meldrum.

At the Brighton meeting (1872) it was stated that the cyclones of the Indian Ocean between the Equator and lat. 25° S., were much more frequent during the maxima than during the minima sunspot years. Since that time the subject has been more fully examined, and I now beg to present a catalogue of all the cyclones known to have occurred during the last twenty-six years. The Tables given last year only contained cyclones of sufficient violence to dismast or otherwise disable vessels at sea, whereas the accompanying Catalogue gives all the cyclones of force 9 to 12, that is, "strong gale" to "hurricane."

The number of cyclones for each year from 1847 to 1873, is as follows:—

	Years.	No. of Hurricanes.	No. of Storms.	No. of Whole Gales	No. of Strong Gales.	Total No. of Cyclones.	No. of Cyclones in Max. and Min. Periods.
	1847	5	0	0	0	5	
Max.	1848	6	2	0	0	8	
	1849	3	2	3	2	10	26
	1850	4	3	1	0	8	
	1851	4	2	1	0	7	
	1852	5	0	3	0	8	
	1853	1	1	5	1	8	
	1854	3	1	0	0	4	
Min.	1855	3	2	0	0	5	
	1856	1	0	2	1	4	13
	1857	2	1	1	0	4	
	1858	3	1	3	2	9	
Max.	1859	3	2	6	4	15	
	1860	7	4	2	0	13	39
	1861	5	2	2	2	11	
	1862	4	2	2	2	10	
	1863	5	2	1	1	9	
	1864	2	2	1	0	5	
	1865	2	2	3	0	7	
Min.	1866	1	4	2	1	8	
	1867	0	4	2	0	6	21
	1868	3	2	2	0	7	
	1869	3	1	3	2	9	
	1870	2	1	5	3	11	
Max.	1871	3	2	3	3	11	
	1872	6	5	1	1	13	36
	1873	4	5	3	0	12	

The observations for the years 1847-1850, are probably not so complete as those for the subsequent years during which the Meteorological Society of Mauritius made it a special duty to collect storm statistics. Still it is evident that not only the years 1860 and 1872, but also the year 1848, were remarkable both for the number and violence of cyclones, while the years 1856 and 1857 were quite the reverse. By taking the number of cyclones in each maximum and minimum sunspot year, and in each year on either side of them, so as to form maxima and minima periods of three years each, we obtain the results given in the last column of the above table, showing that during the maxima periods 1848-1850, and 1859-1861, the number of cyclones was 65, whereas in the minima periods 1855-1857, and 1866-1868, it was only 34, or little more than one half. In 1856, there was only one hurricane of small extent, and in 1867, no hurricane at all. Indeed it is doubtful whether several of the cyclones in those years classed under "storms," should not have been put down in the columns of "whole gales" and "strong gales."

As, during the last twenty-two years, information respecting the hurricanes of the Indian Ocean has been carefully and systematically collected and tabulated, I believe that the results now given are substantially correct, and it seems to me that they point unmistakeably to a close connection betwen sunspots, or solar cyclones, and terrestrial cyclones, or what might be called earth-spots, by an observer, on another planet.

Most of the severest cyclones have already been traced, and the others will also be traced. When this shall have been done, an attempt will be made to express numerically the amount of cyclonic area and cyclonic force for each year. The catalogue gives little more than the number of cyclones, but from what is already known, there is little doubt that their extent and force were also far greater in the maxima than minima years.

Being desirous of extending the investigation as far back as possible I have been examining the lists of former hurricanes, and it is interesting to find that the evidence from this source strongly corroborates the correctness of the conclusions deduced from the observations of the last twenty-six years. From a "chronological table" published in the "Mauritius Almanack" of 1869, we obtain the following list of Mauritius hurricanes:—

Years	No. of hurricanes	Years	No. of hurricanes
1731	1	1818	1
1754	1	1819	2
1760	1	1824	2
1766	1	1828	1
1771	1	1829	1
1772	1	1834	1
1773	1	1836	1
1786	1	1844	1
1806	1	1848	1
1807	2	1850	1
1815	1		
		Total	24

Probably the above list gives only the hurricanes that were remarkable from their destructive effects in the island; and much stress should not be laid on observations taken at a single locality. But it is rather suggestive that out of the twenty-four hurricanes mentioned, seventeen fall within, or very nearly within, maxima sun-spot periods, and only seven within minima periods. Thus:—

Max. Years	No. of hurricanes	Min. Years	No. of hurricanes
1760	1	1731	1
1771		1754	1
1772	3	1766	1
1773		1824	2
1786	1	1834	1
1806		1844	1
1807	3		
1815		Total	7
1818	4		
1819			
1828			
1829	2		
1836	1		
1848			
1850	2		
Total	17		

The same "chronological table" contains the following remarks:— 1760, Dec. 1, "Meteorological Phenomena," 1815, Feb. 5, "Meteorological Phenomena."—I have not ascertained what these phenomena were; but it is not improbable that they were auroras. The aurora of the 4th Feb., 1872, was described in the newspapers as a *phénomène météorologique.*

Baron Grant, in his History of Mauritius, p. 194, regrets the destruction of the woods near Port Louis, because, he says, the town was thereby "exposed to the violence of the winds, as well

as to the heat of the sun;" and in a foot-note it is remarked: "These inconveniences, however, are fully counterbalanced, if it be true that the *cessation of hurricanes since* 1789 has been caused by the great diminution of the woods." As the history was published in or after 1801, it would appear that during the twelve years 1789–1801 no hurricanes occurred. Now, since according to the Table of Sunspots the years 1788 and 1804 were maxima years, and the intervening minimum occurred in 1798, our theory would lead us to expect a comparative cessation of hurricanes during the period mentioned.

If time permitted, I would adduce similar evidence respecting the hurricanes of Bourbon and other parts of the world.

The hurricanes of the Indian Ocean are well known to be attended with torrential rains. So much is this the case that the popular belief at Mauritius is that cyclones are the cause of our rains. Heavy rains over extensive areas are certainly concomitant with cyclones in the Indian Ocean, and it was therefore resolved to examine whether there was a rainfall periodicity. As far as the Mauritius observations went, the matter was clear; but it was desirable to extend the investigation to other localities. The Queensland and South Australia observations, which were the only ones available at the time, gave a similar result, and as Adelaide is far beyond the limits of the region of cyclones, it was surmised that there was a rainfall periodicity generally. The Cape observations afterwards gave additional support to this view. The rainfall of England was next examined, and also found to bear out the hypothesis.

It would occupy much more time than I can at present spare to enter fully into this question of rainfall periodicity. With the help of the researches of Mr. Lockyer, Mr. Symons, and Dr. Jelinek of Vienna, I have now examined 93 tables of rainfall for various parts of the world, and I find that, scarcely without exception, more rain falls in the maxima than in the minima sunspot years. I beg to append a table showing the general results for the quarters of the globe. It will be seen that, so far as the observations go, Europe, Africa, America, and Australia give very favourable results. Asia is only represented by three stations, one of which is Jerusalem, where the excess of rain in one minimum period exceeds the excess in the maxima periods for two stations in India. France is the only European country (of which the rainfall has been examined) that gives an unfavourable return, but it must be remarked that we have as yet got only five stations there, which are all inland, and probably do not fairly represent the rainfall of the whole country.

By taking the longest possible series of observations for several stations, the periodicity comes out, and there is, I think, strong evidence that the rainfall for the whole globe is subject to an annual variation.

Having given the facts, as far as I have been enabled to do so, I abstain from offering any theoretical remarks. If cyclone and rainfall periodicities be fully established, a corresponding (direct) temperature periodicity should exist, and this presumable variation of solar heat may be the indirect cause of the periodicity of auroras and magnetic disturbances.

(The catalogue of cyclones was appended.)

On the Effect of Pressure and Temperature on the Widening of the Lines in the Spectra of Gases, by Arthur Schuster, Ph. D.

One of the questions in Spectrum Analysis yet open to discussion, is what influence pressure and temperature exert on the widening of the lines, which is sometimes observed when an electric current passes through certain gases. The subject of this communication is to point out a little ambiguity which has crept into the very statement of the question at issue, and to show the only way by which a decisive answer can be arrived at, and, in my opinion, has already been arrived at. I shall begin by assuming that the convection of electricity has no direct influence on the character of the spectrum; that is to say that under the same pressure, and at the same temperature, the gas will always show the same spectrum, whether the temperature has been produced by the passage of an electric current or by any other means. In the present state of science this is the only reasonable assumption that can be made, and it has been tacitly made, I think, by every one who has written on the subject.

Let us imagine a vessel filled with hydrogen, and let the temperature of the gas be brought up to incandescence. The heat communicated to the vessel is partly used to increase the translatory motion of the gas, and thereby to increase its pressure, and the other part of the heat has increased the periodical motion in the molecules of the gas, which is generally admitted to be the cause of its incandescence. If the temperature is such that the lines are widened we can account for this fact in two different ways. We may think that the forces which maintain the molecule in vibration, and which are such that at a lower temperature only perfectly isochronous vibrations can take place are somewhat altered, so that the bonds which keep the molecules together are loosened and now allow vibrations to take place, the period of which is somewhat altered and varying. We might secondly explain the widening of the lines by saying that they are caused by the disturbances caused by the frequent shocks of other molecules. If we increase the number or the force of these shocks by increasing either the number of molecules or their velocity we might well obtain disturbances large enough to change a little the period of vibration. These are the only two explanations that can be given, and if we say, therefore, that temperature is the cause of the widening of the lines we can only mean that part of temperature which has its equivalent in the vibrating energy within one molecule. If we say that pressure is the disturbing cause we include that part of heat which increases the pressure with increasing temperature. Let us now see whether we can obtain a clear answer to the question which has now been clearly put.

It is evident that no result can be arrived at by subjecting the same quantity of gas in the same vessel to different temperatures, for we cannot increase the vibrating energy of the molecules without increasing at the same time and in the same proportion (as Clausius has shown), their translatory velocity. By varying in the same ratio the two possible causes we shall never be able to say which is the right view to be taken.

There are two ways open to us to mend this difficulty. We might increase the temperature of the gas *under the same pressure*. If the perturbation caused by the shocks of other molecules cause the widening of the lines this widening ought not to take place as we have reduced the number of these shocks in the same ratio as we have increased their force. If on the contrary the disturbance in the period of vibration has its cause within the individual molecules it ought to remain.

We might, secondly, decide the question in subjecting the gas at the *same temperature* to different pressures. If perturbations are the cause the lines would be widened. Which of these two ways is most easily pursued in experimenting? Can we easily heat up a gas to incandescence under constant pressure? I think not. If an electric discharge takes place in a gas only comparatively few particles of the gas are heated up, and at a very small distance from the points through which the discharge takes place the gas is hardly heated up at all. But if the heat is not diffused through the whole mass of gas, the increase of pressure caused by this gas will also be merely confined to the luminous streak, and we can therefore obtain no answer to our question (as this has been attempted) by filling a tube with a certain quantity of gas, and altering the strength of the passing current or the mode of discharge.

We are, therefore, compelled to abandon this route and to turn our eyes to the second way which I have indicated; but here we meet another difficulty, and even one over which we cannot easily get. We cannot alter the pressure of a gas without altering its electric resistance, and, therefore, also the strength of the electric current and the heat developed. We can only decide the question by subjecting the gas at the *same* temperature to different pressure. Now have there ever been any such experiments made? I think there have, and even very decisive ones. Frankland and Lockyer have found that if we increase the pressure of hydrogen while an electric current is passing through it the lines begin to expand till the spectrum becomes continuous, and finally the resistance becomes so large that the electric current will not pass at all. On the other hand Gassiot and Plucker have observed that if we diminish the pressure of hydrogen its electric resistance force diminishes, attains a minimum, then increases again, and if we keep up exhausting the tube it becomes again so great that the current cannot pass. Plucker says that a tube exhausted to its utmost limits shows the lines of hydrogen and silica. He mentions at one place, I think, that the lines are very fine and distinct. If there would have been any widening he would have been sure to mention it. Now it is not too much to assume that the resistance of the gas at the moment when the discharge just ceases to take place is the same whether the increase of resistance is produced by too great a pressure or too great an exhaustion. At this moment, therefore, the current is the same and the same energy must be converted into heat by resistance. But in the case in which the current does not pass on account of the excessive diminution of pressure, only a much smaller

quantity of gas has to be heated than in the other case. It must, therefore, be heated up to a much higher temperature, and yet the spectrum is not continuous and the lines are not even widened. We are, therefore, compelled to accept Frankland and Lockyer's original conclusion, that pressure and not heat is the cause of the widening of the lines.

The question is one of considerable importance. If temperature would widen the lines, the widening ought always to begin at the same temperature, and the hydrogen in the solar protuberances which show only narrow lines could not be at a higher temperature than the hydrogen in our vacuum tubes, the moment the lines begin to widen. If our conclusion, however, is correct the breadth of the lines will give us no indication whatever as to the temperature of the gas.

Dynamometers, by R. S. Ball, LL.D., F.R.S.

If we adopt that force which acting on one gramme for one second will impart the velocity of one centimetre per second as the unit, then one million of such units is a convenient magnitude for practical purposes. The large figures on the dynamometers represent these million units, for which it is hoped that ere long a suitable name will be adopted. The dynamometers are intended for educational purposes. They are exhibited to the Association with the desire of aiding the present movement in favour of an improved system of fundamental unity.

SECTION C.—Geology

Concluding Report on *the Maltese Fossil Elephants*, by Dr. A. Leith Adams, F.R.S.

For thirteen years Dr. Leith Adams has prosecuted his researches upon the fossil elephants of Malta, and he now presented the final report upon this subject. Three forms of fossil elephants occur here which are unknown elsewhere, all of small size. The largest is the *Elephas Mnaidriensis* (L. Adams), which attained a height of seven feet. In the crown sculpturing of the molars this species resembles *Elephas antiquus*; as regards the ridge-formula, its nearest ally is *Loxodon meridionalis. Elephas Melitensis* (Falconer and Burk) varied in size; its average height was about five feet; this too belonged to the Loxodon group. The smallest bones known to the author belonged to an elephant only three feet high, called *Elephas Falconeri*, by Busk. Although there appears to be some evidence for separating this from the other forms, yet the author stated that "there is no difficulty in arranging a graduating series of specimens from the smallest up to the largest bones ascribable to the *Elephas Melitensis*."

The elephants all occur in the same deposit, and with them there are remains of *Hippopotamus Pentlandi* and *H. minutus*. There is also a gigantic dormouse and a large extinct swan, besides some reptilian remains not yet fully worked out.

The report concludes as follows:—"It must be apparent that this (for the most part) unique fossil fauna restricted to a small mid-ocean island, presents several interesting contrasts with reference to the Mammalia in general, and elephants in particular, which frequented Europe during late geological epochs. For example, between Rome and Sicily we find remains of the *Elephas primigenius, Elephas antiquus*, and *Elephas meridionalis*. In the caves of Sicily, traces of the African elephant have been discovered, and also molars, barely distinguishable from those of the Asiatic species, and which, under the name of *Elephas Armeniacus*, are traceable eastward into Asia Minor, in the direction of the present habitat of the living species. It looks, indeed, as if the eastern basin of the Mediterranean had been at one time a common ground where all these extinct and living elephants met, and from whence, with other animals, they have disappeared or been repelled to distant regions."

Sub-Wealden Exploration.—1. *General Report*, by Henry Willett.

In this report Mr. Willett gave a summary of the results achieved up to the present time, the details having already been published in his quarterly reports.

The boring was commenced at the time of the last meeting of the British Association at Brighton, and its object is to explore the rocks underlying the Weald of Sussex. A bore of $6\frac{1}{2}$ inches diameter was at first adopted, but at the urgent recommendation of Mr. Prestwich, one of 9-inch diameter was employed. The bore has now reached a depth of 300 feet, and the engineer (Mr. Bosworth) has contracted to increase it to a depth of 418 feet at the cost of only 1*l.* per foot. Of the 300 feet of strata already passed through, about 70 were previously known, but the remaining 230 are new to science; 50 feet of this consists of valuable beds of gypsum.

Mr. Willett has designed a novel form of drill which possesses the following advantages:—(1) It cuts only the circumference; (2) it makes better progress; (3) the central core is left intact; (4) the tool not unfrequently extracts the core itself. The gypsum was extracted by this means, and it is believed that no such cores have been brought to the surface from similar depths in this country.

Sub-Wealden Exploration.—2. *Geological Report*, by W. Topley, F.G.S.

The author commenced by repeating the protest, often made already, that the Sub-Wealden Exploration was not a "search for coal." It is simply an endeavour to explore the rocks which underlie the Weald and especially to reach the Palæozoic rocks. Whatever these rocks may prove to be, if reached at all, the boring will have succeeded. The results of this boring cannot fail to have important bearings upon the question of the probable occurrence of coal measures beneath the South-East of England, but the discovery of coal is not the object in view.

An account was then given of the lowest beds exposed at the surface in Sussex, and of the reasons which have led many geologists to consider them as representatives of the Purbeck Beds. The thickness of Purbeck Beds previously known in Sussex was somewhat over 300 feet; probably about 230 additional feet of strata have been made known by the boring, in which there are some valuable beds of gypsum.

The boring commences about 250 down in the known Purbeck Beds; up to Sept. 1 it had reached a depth from the surface of 294 feet. It is not safe at present to speculate upon the geological age of the lowest beds reached in our boring, but additional evidence will probably soon be obtained.*

The author then pointed out that most of the bore holes which have been put down to the Palæozoic rock through newer strata have reached those older rocks at about 1,000 feet below the sea. There is a probability then that at or about this depth the palæozoic rocks will occur beneath the Weald. These places, however, are on, or to the north of, the westerly prolongation of the Axis of Artois, whilst the boring is to the south of that line; it is therefore possible that different conditions may prevail here.

Attention was then drawn to the fact, already pointed out by Mr. Godwin-Austen, that the dip of the carboniferous limestone in the Boulonnais is to the south, whilst in the Pays de Bray the same limestone has been found at a depth of 57 feet from the surface, underlying Kimmeridge clay. It is then probable that under the secondary rocks near to the south of Boulogne there is a basin of palæozoic rocks, in which the coal measures may be preserved; this basin might possibly be prolonged to the west below the Wealden district of the south-east of England.

In the course of the discussion which followed the reading of these reports, Sir John Hawkshaw stated that many people, himself included, took an interest in this question chiefly from the hope that coal might be found; but even if in this respect we were doomed to disappointment it would still be of great importance to show that, at that particular spot, no coal existed. Prof. Phillips thought that the object sought was neither coal, gypsum, nor salt; but that *something* exists below the Wealden is certain, and that something we are now searching for. A discussion then took place as to the best mode of conducting deep borings. Mr. R. Russell, C.E., spoke of the great value of the diamond boring process; but from remarks made by other speakers it appeared that, although the diamond is admirably adapted for boring small holes in hard rocks, it is not so well suited for conducting such an operation as that under discussion.

On the Arenig and Llandeilo Rocks of St. David's, by Henry Hicks, F.G.S.

The object of this paper was to follow out the succession of the rocks in the neighbourhood of St. David's, commenced in previous papers communicated to the British Association. The section was now completed to the top of the Llandeilo series. The Arenig and Llandeilo groups were each divided into an upper and a lower series, the author believing that in each case

* Since this Report was read, Prof. Phillips has broken up and carefully examined parts of the cores brought up from the bottom of the boring: in them he has found *Lingula ovalis*, which occurs in the Kimmeridge Clay. (See p. 487.)

there was sufficient evidence to enable him to do so. The Lower Arenig series it was stated occur as black slates and flags about 1,000 ft. in thickness, and are characterised by many species of graptolites as well as by numerous trilobites entirely restricted to the series. The Upper Arenig series occur as fine-grained, soft black shales, not much cleaved, also about 1,000 ft. in thickness, resting conformably on the Lower Arenig series. Their graptolites are distinct from those found in the lower beds, as are also all the other fossils. The Lower Llandeilo series, the lowest rocks recognised by Sir R. I. Murchison in the typical Llandeilo district, occur at St. David's as black slates and hard grey flaggy sandstones, and are about 1,500 ft. in thickness. The most characteristic fossils are *Didymograptus Murchisoni*, *Diplograptus pristis*, *Asaphus tyrannus*, *Calymene Cambrensis*, and *Illænus perovalis*. The Upper Llandeilo series occur as black slates and flags, several thousand feet in thickness, forming several folds of strata, and resting conformably on the Lower Llandeilo series. The typical fossils are *Ogygia Buchii*, *Barrandea Cordayi*, *Calymene duplicata*, *Cheirurus Sedgwickii*, *Trinucleus fimbriatus*, *Ampyx nudus*, and *Lingula Ramsayi*.

The author doubted whether any other spot hitherto examined in Britain could show so continuous a section of these rocks; still he believed that there was ample evidence to prove, from researches made in other parts of Wales and in Shropshire, that the succession here made out was, in most of its important details, capable of being applied to many other districts.

SECTION D.—BIOLOGY

DEPARTMENT OF ANTHROPOLOGY

On the Relation of Morality to Religion in the Early Stages of Civilisation, by Edward B. Tylor, F.R.S.

Investigations of the culture of the lower races of mankind show morality and religion subsisting under conditions differing remarkably from those of the higher barbaric and civilised nations. Among the rudest tribes a well-marked standard of morality exists, regulating the relations of family and tribal life. There also exists among these tribes some more or less definite religion, always consisting of some animistic doctrine of souls and other spiritual beings, and usually taking in some rudimentary form of worship. But, unlike the higher nations, the lowest races in no way unite their ethics and their theology. As examples, the Australians and Basutos of South Africa were adduced. The Australians believe spiritual beings to swarm throughout the universe; the Basutos are manes-worshippers, considering the spirits of deceased ancestors to influence all the events of human life, wherefore they sacrifice to the spirits of near relatives, that they may use their influence with the older and more powerful spirits higher in the line of ancestry. Yet these races and many others have not reached the theological stage at which man's good or evil moral actions are held to please or displease his divinities, and to be rewarded or punished accordingly. The object of the present paper is to trace the precise steps through which the important change was made which converted the earlier unethical systems of religion into ethical ones. This change appears to have been a gradual coalescence between the originally independent schemes of morality and religion.

In order to show the nature of such coalescence between religion and other branches of culture, not originally or not permanently connected with it, the author traced out on an ethnological line the relations between religion, and on the one hand the rite of marriage, on the other hand the profession of medicine.

First as to marriage:—The evidence of the lower races tends to show that at early stages of civilisation, marriage was a purely civil contract. Its earliest forms are shown among savage tribes in Brazil and elsewhere. The peaceable form appears well in the customs of the marriageable youth leaving a present of fruit, game, &c., at the door of the girl's parents; this is a clear symbolic promise that he will maintain her as a wife. Another plan common in Brazil is for the expectant bridegroom to serve for a time in the family of the bride, till he is considered to have earned her.

The custom of buying the wife comes in at a later period of civilisation, when property suited for trade exists. The hostile form of marriage, that by capture, has also existed among low tribes in Brazil up to modern times, the man simply carrying off by force a damsel of a distant tribe; the antiquity of this "Sabine marriage" in the general history of mankind being shown by its survival in countries such as Ireland and Wales, where within modern times the ceremony of capturing the bride in a mock fight was kept up.

Now in none of these primitive forms of marriage, as retained in savage cultures, did any religious rite or idea whatever enter. It is not till we reach the high savage and barbaric conditions that the coalescence between marriage and religion takes place; as where among the Mongols the priest presides at the marriage feast, consecrates the bridal tent with incense, and places the couple kneeling with their faces to the east to adore the sun, fire, and earth; or, as where among the Aztecs the priest ties together the garments of the bridegroom and bride in sign of union, and the wedded pair pass the time of the marriage festival in religious ceremonies and austerities. So complete in later stages of culture did this coalescence become, that many have come to consider a marriage hardly valid unless celebrated as a religious rite and by a priest.

Second, as to the relation of the profession of medicine to religion. In early animistic philosophy, one principal function of spiritual beings was to account for the phenomena of disease. As normal life was accounted for by the presence of a soul operating through the body, in which it located itself, so abnormal life, including the phenomena of disease, was accounted for in savage and barbaric culture as caused by some intruding spirit. Thus spiritual obsession and possession becomes the recognised theory of disease, and the professional exorciser is the doctor curing disease by religious acts intended to expel or propitiate the demon. Since the middle period of culture, however, this early coalescence has been gradually breaking away, till now in the most civilised nations the craft of healing has become the function of the scientific surgeon or physician, and the belief and ceremonies of the exorcist survive in form rather than in reality.

By these cases it is evident that coalescence between religion and other matters not necessarily connected with it may take place at different periods of culture, and also that this coalescence may terminate after many ages of adhesion. Having shown this, the author proceeded to ascertain exactly when and how in the history of civilisation the coalescence of morality and religion took place.

First, where manes-worship is the main principle of a religion, as among some North American tribes and the Kafirs of South Africa, the keeping up of family relations strongly affects the morality. It is, for instance, a practice among the ruder races to disinter the remains of the dead or to visit the burial place, in order to keep the deceased kinsman informed as to what takes place in his family, in which he is often held to take the liveliest interest. Thus it is evident that any moral act of an individual damaging to his family would be offensive to the ancestral manes, whose influence must therefore strengthen kindly relations among the living members of the tribe. Higher in the social scale this ethical influence of manes-worship takes more definite form, as when in China the divine ancestor of an emperor will reproach him for selfish neglect or cruelty to his nation, and even threaten to induce their own highest divine ancestor to punish him for misdeeds. Thus amongst the ancient Romans, the Lares were powerful deities enforcing the moral conduct of the family, and punishing household crime.

Second, the doctrine of the Future Life begins at the higher levels of savagery to affect morals. In its first stage the doctrine of metempsychosis is seen devoid of moral meaning, men being re-born as men or animals, but when the distinction appears in the higher savagery between migration into vile or noble animals, it is not long before this distinction takes the form of reward or punishment of the good and wicked by their high or low re-incarnation, an idea which is the basis of the Buddhist scheme of retributive moral transmigration through successive bodies. In its earlier stages this doctrine was of mere continuance, as where South-American tribes expected the spirits of the dead to pass to another region where they would live as on earth. Here the distinctions of earthly rank are carried on, the chief's soul remaining a chief, and the plebeian's soul a plebeian, but no sign of moral retribution appears. The first stage of this seems to be where warriors slain in battle are admitted to the paradise of chiefs in the land of the Great Spirit. This idea, which comes into view in several districts, leads to the fuller moral scheme in which goodness of any kind—valour, skill, &c.—are more and more held to determine the difference between the next life of the good man in happy hunting-grounds, or of the bad man in some dismal wilderness or subterranean Hades. In

the higher nations this element becomes more and more distinctly marked, till the expectation of future reward and the fear of future punishment becomes one of the great motives of human life.

Third, when theology among the rudest tribes is mostly confined to consideration of ghosts, demons, and nature-spirits, the intercourse with these leads to little inculcation of moral action. It is when ideas of the great deities become predominant, when men's minds are turned to the beneficent action of the sun, or heaven, or earth, or to a Supreme Deity yet above these, that it is conceived that the order of nature includes moral order of human conduct. Then, as in the religion of ancient China, the universe and its Supreme Deity are regarded as furnishing the model and authority regulating man's actions towards his kindred and his subjects. Thus appears, not in the beginning, but in the middle of the development of religious ideas among mankind, the leading principle of a moral government of the world and its inhabitants.

In these three ways it appears from the evidence of ethnology that the vast transition was made from the earlier unethical to the later ethical systems of religion. Its course, so different from that imagined by the older speculative theologians, has to be ascertained from examination of the actual stages through which the religions of the world have passed. The very attempt to make this investigation on a basis of facts is, however, a novelty.

SCIENTIFIC SERIALS

THE *Monthly Microscopical Journal* commences with an article, illustrated with a plate, "On Organic Bodies in Fire Opal," by Mr. H. J. Slack, in which the author, from the appearances which he finds and describes, expresses an opinion, though not a decided one, that these minute bodies may be vegetable fossils, possibly algæ, though the evidence he adduces is extremely slight. Dr. G. W. Royston Pigott continues his researches on the high-power definition of organic particles, and re-affirms that the generally received description of the Podura scale is erroneous, on account of the employment of spherically over-corrected objectives.—Mr. Wenham criticises Dr. Pigott's paper in the preceding number of the Journal, remarking truly that the patience of microscopists must eventually become exhausted by the repetition of the same theme. He then shows that Dr. Pigott claims, without foundation, discoveries with regard to the improvement of object-glasses and the "colour test."—Dr. Maddox, On the apparent relation of nerve to connective-tissue corpuscles, &c., in the Frog-Tadpole's Tail, describes, in connection with the observations of Eberth, Kuhne, and Moseley, cases in which nerve-fibres seem to lose themselves in connective tissue corpuscles. His results are not very decided, and hardly tend to settle the question.—Mr. Edwin Smith describes a new sub-stage for the microscope, and certain appliances for illumination.—The paper read before the Royal Society, by Messrs. Pode and Lankester, is given in full. Their experiments are divided into eight series, in which infusions of hay and turnip, mixed or unmixed, with cheese finely divided or in lumps, are boiled and some of them sealed. When the cheese was finely comminuted, Bacteria did not appear; when in lumps, they were frequently found. In a boiled turnip infusion, placed in a retort of which the end was left open, there was no cloud developed after many weeks, which is quite contrary to the observations of Dr. Bastian (NATURE, Feb. 6, p. 275.)

THE *Geological Magazine* contains Prof. T. Sterry Hunt's article from the *Canadian Naturalist*, on the history of the names Cambrian and Silurian in Geology. The subject is divided into three parts: 1. The history of Silurian and Upper Cambrian in Great Britain from 1831 to 1854. 2. That of the still more ancient rocks in Scandinavia, Bohemia, and Great Britain up to the present time. 3. The history of the Lower Palæozoic rocks in North America.—Mr. E. Hardman describes and gives analyses of the Siliceous Nodular Brown Hæmatite (Göthite) in the Carboniferous Limestone Beds near Cookstown, Co. Tyrone. The ore contains as much as 52·2 per cent. of iron, on the average, and no sulphur.—Mr. J. C. Mansel-Pleydell has a brief memoir on the geology of Dorsetshire, which is an interesting summary of the most important points in the unbroken series from the Liassic to the Quaternary formations found in the county.—Mr. Joshua Wilson, in endeavouring to arrive at the time when the Gulf Stream reached the British Coast and so dispersed the then abundant glaciers, ingeniously shows that a raised beach, containing Arctic shells, mentioned by Geikie in his "Scenery of Scotland," must have been produced before that event, otherwise i would have been removed by the *offshore* under-current which always accompanies an onshore wind.—Dr. Winkler's description of *Pterodactylus micronyx* in the Jeyler Museum, from the Lithographic Stone of Eichstätt, in Bavaria. The specimen is very small and complete. There are four phalanges in the long finger of the hand. In the foot there are two in hallux; three on the second and third; and two, with no metatarsus, on the fourth (Stümmel).—In a letter to the editor, Mr. T. W. Danby, after comparing the new method of writing crystallographic formulæ proposed by Mr. Rutley, shows that it is not so advantageous as that of Dr. Whewell, modified by Prof. W. H. Miller; it is therefore doubtful whether its partial acceptance will not place a further obstacle in the student's path.

THE numbers of the *Journal of Botany* for August, September, and October, fully maintain the character of this magazine. In addition to the short notes and queries in each number, which often contain points of great interest to the systematic or physiological botanist, the following articles may be mentioned as of special value:—Dr. Alfred Nathorst, of the Geological Survey of Sweden, contributes a paper on the Distribution of Arctic plants during the Post-Glacial Epoch, which he considers to exhibit gradual changes of climate from the Forest-bed down to the Boulder-clay.—Prof. Church gives an analysis of the giant puff-ball, *Lycoperdon giganteum*, which he finds to contain, when dried, as much as 66·78 per cent. of albuminoids, and the ash 46·19 per cent. of phosphorus pentoxide.—Mr. J. G. Baker describes a very interesting new genus of ferns, *Diplora*, of the tribe *Asplenieæ*, from the Solomon Islands.—From the same botanist we have a valuable synopsis of the East Indian species of *Dracæna* and *Cordyline*.—Mr. J. Ball commences a description of some of the new species, sub-species, and varieties of plants collected by Dr. Hooker and himself in Morocco in 1871; the flora belongs essentially to the Mediterranean type, and the number of novelties is not comparatively large.—Mr. Carruthers gives his very valuable annual Review of the Contributions to Fossil Botany published in Britain in 1872, comprising 23 distinct papers or abstracts.—In these numbers we have also parts vi. and vii. of the Rev. E. O'Meara's Recent Researches in the Diatomaceæ.

THE second part of vol. xxix. of the *Transactions of the Linnæan Society*, just published, is occupied by a continuation of Colonel Grant and Prof. Oliver's "Botany of the Speke and Grant Expedition." The number of new species described in this part is thirty-five; and it is illustrated by thirty-five full-sized 4to plates, the expense of which is munificently borne by Col. Grant.

Der Naturforscher, August.—The eruption of Vesuvius last year attracted much scientific observation, and we have in the present serial an abstract of a valuable paper by M. Heim on the nature and formation of lava, of which he distinguishes two kinds, "lump" lava and "cake" lava (*Schollen* and *Fladen*), differing, he found, not in chemical constitution, but merely in vapour-contents. In the physical division we may note M. Wiedemann's experiments in measuring the elliptical polarisation from reflection on bodies with surface colours, for a series of angles of incidence, and different parts of the spectrum. Meteorology is represented by M. Dufour's recent observations on reflection of solar heat from the Lake of Geneva; and an interesting paper entitled "Polar Lights and Earth Lights." There is a description of M. Zöllner's new mode of estimating the absolute temperature of the sun, which is based simply on a knowledge of the density relation between two different layers of the hydrogen atmosphere, the distance between them being known. The value his formula gives is 61350°. Among botanical subjects treated are, autumn colouring of leaves and formation of vegetable acids, summer dryness of our trees and shrubs, and passage of radiant heat through leaves. Some physiological experiments by M. Rosenthal, on the time-relations of reflex phenomena, are described; and there is a variety of other matter, much of which has already been noticed in these columns.

Annalen der Chemie und Pharmacie. Band. clxviii. Heft. 1, July 16.—The number opens with four papers by Prof. Ad. Claus, on azophenylen, on di-iodhydrin, on the action of ammonia on dichlohydrin, and on the preparation of dichlorhydrin. The first of these contains a long and exhaustive account of the body in ques-

tion and of its compounds. The formula of azophenylen is $C_{12}H_8N_2$. By the action of ammonia on it a body having the formula $C_{12}H_{10}N_2$ is produced.—On diiodhydrin, by the same author. This body has the formula $C_3H_6I_2O$.—On the action of ammonia on dichlorhydrin, by the same. The result of the action is the production of chlorhydrinimid, a body of the formula $C_{12}H_{27}N_3Cl_2O_4$.—Preparation of dichlorhydrin, by the same. The method consists in acting on glycerin with chloride of sulphur.—Application of the periodic law to the cerium group, by D. Mendelejeff.—On the preparation of ethylen and its bromide, by E. Erlenmeyer and H. Bunte.—On the action of nascent hydrogen on the oil of bitter almonds, by Hugo Amann.—On the bromised benzol sulpho acids, by A. Woelz. The author has prepared dibrombenzol sulpho-acid, and gives an account of its salts and of its reaction with fused potassic hydrate.—An investigation of piperin and its products of decomposition, piperic acid and piperidin, by R. Fittg and I. Remsen.—On ethylen-protocatechuic acid by the same author, and T. Macalpine.—New compound of the Naphthalin group, by J. P. Battershall.—On the action of a mineral sulphur water on cast-iron, by Dr. E. Priwoznik. The author found an iron water-pipe, through which this wa·r passed converted as regards its inner side into a mixture of sulphide of iron, hydrated oxide of iron and free sulphur. The centre stratum was also altered, containing only 79·2 per cent. of iron.—On sulph-hydantoin (glycolyl-sulpho-urea) by R. Maly.—Determination of boiling points at the normal barometric pressure, by Dr. H. Bunte.—Preparation of trimethyl-carbinol, by Linnemann's method, by A. Butlerow.

SOCIETIES AND ACADEMIES

London

Royal Microscopical Society.—The opening meeting of the session was held at King's College, Oct. 1, C. Brooke, F.R.S., president, in the chair.—The secretary read a paper by Dr. Maddox descriptive of an organism found in a pond of fresh water in the New Forest, near Lyndhurst, which it was proposed to name *Pseudo-amœba violacea*. The general appearance of the organism was minutely described and figured, and the results of a series of continuous observations upon a growing slide under the microscope were detailed.—A paper by Mr. F. Kitton, of Norwich, describing some new species of Diatoms, was taken as read, and the attention of the meeting was called by the president to one of great beauty named by Mr. Kitto *Aulacodiscus superbus*.—Mr. F. H. Wenham made some interesting observations upon the microscopical appearance of glass which had been subjected to the action of the American sand-blast process, showing that the erosion of the surface was entirely due to the percussive force of the particles of sand, and that the results of this were demonstrated by the polariscope. A number of specimens were exhibited in the room.—Mr. C. Stewart, the hon. sec., exhibited under the microscope, and minutely described, a beautiful preparation of the spermatophores of the common squid; he also explained and illustrated the general structure of the generative organs of the male cuttle-fish.

Philadelphia

Academy of Natural Sciences, April 3.—*Conchological Section.*—Dr. W. S. W. Ruschenberger, in the chair.—Dr. F. A. Hassler presented the following memorandum of experiments by W. M. Gabb and himself to ascertain the tenacity of life in *Littorina muricata*. The specimens, 140 in number, were collected by Mr. Gabb in St. Domingo, September 1870, and hung in a basket in his office. A few (five or six) were moistened after three months, then each month until May 1871, when all were alive. May, June, July, and August, 1871, 25 were moistened each month, and all found to be living except two in July and two in August. These were each month laid aside and not moistened again until September. At this time 40 of the original lot remained, all were moistened, and 29 found to be alive. In September, of the 100 which had been moistened during May, June, July, and August, 89 were alive. The 118 living ones were all placed together Feb. 18, 1872, the lot was again moistened and about 60 revived at once, and after several hours all but 24 were or had been crawling. These 24 were rejected. March 30, 1872: of the remaining 94, ten were moistened, nine were alive; these nine were placed aside with a few which had given evidence of life since the last experiment, Feb. 18. Sept. 18, 1872: all moistened and found living; they were also all alive in December. On Feb. 12, 1873, two found to be dead, and were separated from the others. March 26: All moistened, and though exposed for three days, only one began to crawl; this one was separated, also 27 others which were known to be dead, leaving 65 undetermined.

Paris

Academy of Sciences, Sept. 29.—M. Bertrand in the chair.—The following papers were read:—Notes on the yellow elastic tissue, and remarks on its history in relation to a memoir by M. Bouillaud, and some criticisms on it by M. Bouley, by M. E. Chevreul.—Researches on the elastic tissue of the elephant and the ox, by M. Chevreul.—New researches on the analysis and theory of the pulse, by M. Bouillaud. The author continued his former papers on this subject, dealing with the abnormal pulse in this paper.—Remarks on M. Bouillaud's late paper on the pulse, by M. Bouley.—Reply to M. Bouley by M. Bouillaud.—Remarks on No. 21 of the "Mémorial de l'officier du Génie," by General Morin. The general drew attention to many interesting notes on the late sieges of Paris, contained in this number.—Note on magnetism, by M. J. M. Gaugain. This was a fourth instalment of the author's paper.—On the part played by gases in the coagulation of albumin, by MM. E. Mathieu and V. Urbain.—On a new method of treating cholera, and probably yellow fever, by means of sub-cutaneous injections of carbolic acid and carbolate of ammonia, by M. Déclat. The author recommended drinks containing carbolic acid in doses of from thirty to forty centigrammes per day, and from four to six injections of five grammes each of carbolic acid solution (2½ per cent.). These doses are to be largely increased in severe stages of the disease.—Comparison of the *Phylloxeræ vastatrix* of galls with those of roots, by M. Max. Cornu.—On the size and variation of the sun's diameter, by S. Respighi. The author, in his letter, discussed Secchi's late observations on the same subject.—On the action of the respiratory apparatus after an opening of the thoracic wall, by MM. G. Carlet and J. Straus.—On the classification of the fish of the family of *Triglidæ*, by M. H. E. Sauvage.—Researches on the action of heat on the carbuncular virus, by M. C. Davaine.—On a deposit of *Endogenites echinatus* in the Museum (fossil vegetable collection), by M. E. Robert.—On the influence of sulphates in the producton of goitre in relation to an epidemic form of that disease in a barrack at St. Etienne, by M. Bergeret.

THURSDAY, OCTOBER 16, 1873

D'ALBERTIS' EXCURSION INTO THE INTERIOR OF NEW GUINEA

IN a preceding number of NATURE (vol. viii., p. 305) some account has been given of the new Paradise-birds and other novelties recently discovered by Signor Luigi Maria D'Albertis in the interior of New Guinea. Signor D'Albertis, who is now in New South Wales, has lately published in the *Sydney Herald* an account of his month's excursion into the interior of that *terra incognita*, from which the following particulars are taken :—

D'Albertis started from Andai, a small village about ten miles from Havre Dorey, where, along with his companion Dr. Beccari, he had been resident with a Dutch missionary. By the aid of presents to the Corono, or headman of Andai, and promises of further payment on arriving at his destination, he succeeded in obtaining the services of six natives to carry his baggage and provisions to Atam, a populous village in Mount Arfak, where there was a Corono with whom he had already made acquaintance.

An early hour on September 4, 1872, was fixed for the traveller's departure, Dr. Beccari, the botanist, proposing to remain at Andai during the absence of his companion. After crossing a small creek in a canoe, the forest was entered. Besides six natives, D'Albertis was accompanied by a Malay interpreter and the wife of one of the natives, making eight persons in all. After a short walk over level ground a steep hill was reached, and crossed by a narrow pathway, fatiguing and difficult. The forest around was mountainous and gloomy, the silence being relieved only by the deep cooing of pigeons and the hoarse voice of a black Megapode (probably *Megapodius freycineti*). One of the latter served as dinner for the day. After arriving at the summit of the hill, an hour's walk across a level forest-country succeeded, whence a descent was made to a stream of water, deliciously clear and fresh. After this, hills were again ascended, gradually increasing in height, and the road became more and more difficult. Here the Lesser Bird of Paradise (*Paradisea papuana*) was met with, and the large Crowned Pigeons (*Goura coronata*) were very numerous. At 4 P.M. a height of 1,500 feet above the sea, which was seen to the east, not very far distant, had been attained, and after a short descent an extensive watercourse, at this time nearly dry, was reached. Here natives were first encountered ; a tribe of men, women, and children, accompanied by dogs and pigs, emerged from behind the large stones of the water-course. The men were armed with bows and arrows and the *parang*, a large knife, narrowed near the handle and widened towards the extremity. Some of the men approached and were friendly and inquisitive, whilst others kept at a distance, and formed small picturesque groups about the rocks of the watercourse. The women were very timid, and also kept apart in groups along with the children. Upon inquiries through the interpreter, it appeared that these Papuans were returning from an expedition to the sea-side to procure salt. After taking leave of some of the natives, who were going in another direction, D'Albertis accompanied the others to their house, which was situated about 500 feet above the torrent. Here the forest was of the same gloomy character, but relieved by occasional clearings. At sunset a magnificent view over the harbour of Dorey and the island of Mansinam was obtained, and the birds raised their voices in chorus to salute the passing day. The house in which the night was passed contained four families. It was built on trunks of trees and entered by a long ladder. The stranger was well received, and presented with sugar canes, in return for which he gave his hosts tobacco.

The following day (Sept. 5), after some little difficulty, a start was made about 8 A.M., the chief of the house and some women accompanying the party. After descending to the watercourse passed on the previous day, the ascent of Mount Putat was recommenced, under the shade of large and umbrageous trees. At noon, the summit and village of Putat were reached, whence a fine view of the coast of Dorey and island of Mansinam were obtained. To the south-west rose some high mountains covered with dense vegetation. After an interval of repose, our traveller was anxious to depart, but was answered by the natives, that they had already arrived at Atam, and that they were not going any farther. It was not without much difficulty, and Signor D'Albertis showing them by his pocket barometer that they had not arrived at the requisite elevation of the place in question, that it was ultimately arranged that a fresh start should be made on the following morning.

The next day, accordingly, the party quitted the village of Putat, escorted by about 20 additional men, women, and children, and after descending to about 700 or 800 feet above the sea-level, commenced to re-ascend up the bed of another watercourse. About noon, a small stream of fresh water afforded an opportunity for refreshment, and at evening, after a further ascent, night-quarters were discovered in some uninhabited huts. On continuing the journey next day the party still ascended, until the summit of the mountain at an elevation of 3,600 feet was obtained. Here a halt was made in some huts similar to those used for the previous night, and Atam was visible to the west on the farther side of a deep valley. At this spot the Superb Bird of Paradise (*Lophorina atra*) was first seen, but examples were not obtained. To the south of the halting-place lofty mountains arose, considered to be 9,300 feet in height : to the east the view was impeded by thick forests of noble trees.

On continuing the journey a steep and difficult descent of about 900 ft. was made to the bed of a large river, containing more water than other streams previously passed, and said by the natives to flow into the Bay of Geelvink. After following up this river-bed for two or three miles, a rough track led away to Atam, the first houses of which were reached about 3 P.M. Here Signor D'Albertis determined to stop, being much exhausted by the journey, the latter part of which had been rendered fatiguing by the slipperiness of the paths caused by heavy rain. Next day messages were sent for the Corono or headman of Atam, who was resident higher up the mountain. D'Albertis was anxious to proceed farther himself, but his guides refused, stating that they had accomplished their agreement to bring him to Atam, and of this our traveller was satisfied, finding himself now at an elevation of 3,500 ft. above the sea-level.

Whilst waiting for the Corono, D'Albertis rambled about in the vicinity of his habitation, and found a fine young male of the Six-shafted Bird of Paradise (*Parotia sexpennis*), which had never been previously obtained except through native agency, and in imperfect condition. Other examples of both sexes were subsequently obtained, the adult male being always found alone in the thickest parts of the forest, whilst the female and young birds are usually met with at a lower elevation. Respecting this Paradise bird D'Albertis states that it is very noisy and feeds upon various kinds of fruit, more especially on a kind of fig which is very plentiful upon the mountain ranges. To clean its rich plumage, it scrapes a round place clear of grass and leaves, where the ground is dry, and rolls itself in the dust like a gallinaceous bird, at the same time elevating and depressing its plumage, and also raising and lowering the six remarkable plumes on its head, from which it derives its specific name. On the following day (Sept. 9), D'Albertis was fortunate enough to obtain adult specimens of the Six-shafted Paradise Bird just described, and also of the Superb Paradise Bird which he had observed on his way up the mountain. The latter is found on the same mountains, and feeds upon similar fruits; it flies about from branch to branch among the trees of the forest, uttering a cry of "ni-ed, ni-ed," and from this peculiar note is named by the natives, "Niedda," while the Six-shafted Paradise Bird is called "Coron-a." After skinning his Paradise Birds, Signor D'Albertis roasted their flesh for his dinner, and found it of an excellent flavour; his meal, however, was interrupted by the arrival of the Corono and his suite. Hearing a noise at the door, he turned and saw a number of men armed to the teeth. They entered, and defiled before him in silence, laid down their arms, and arranged themselves about the room. They were all adorned with necklaces and bracelets formed of shells, whilst quantities of flowers of bright and rich colours ornamented their hair, ears, and arms. After the men, followed women and children, until the house was full; last of all came the Corono himself, armed like the others, and lavishly adorned with flowers. He was followed by his son and daughter, both albinos, with hair of a clear white colour, eyes blue, and skin very white. Having entertained the Corono with a cup of cognac, Signor D'Albertis received a present of yams, maize, and oranges in return, and was informed that he was welcome to the country. Next day he received numerous visits from natives, and made large additions to his zoological collections. Finding the locality so rich, Signor D'Albertis determined to take an adjacent house, for which a rent of 4 metres of blue calico and four brass bracelets was demanded. On September 11 possession was taken of the new habitation, and the Italian flag hoisted on the summit. The house was divided by some pieces of bark into two rooms, one of which served as a bedroom and a workshop, whilst the other was the reception-room, and also served as a kitchen. When the news spread abroad that a white man had arrived, the visits of the Papuans became very frequent. Most of them brought yams, maize, or tobacco, for which Venetian beads were given in payment. On September 13 the guides who had brought Signor D'Albertis from Andai left him to return home, taking messages to his companion Beccari, to endeavour to send up a new stock of provisions, which were running very short.

Established in his new quarters, Signor D'Albertis set to work on his collections of birds and insects, and succeeded in amassing a large number of interesting specimens. But his provisions quickly began to run short, leaving him only a small quantity of rice to subsist on together with the flesh of the birds prepared for his collections. Salt was not to be had, and powder and shot also began to fail, and endeavours to get a fresh supply of ammunition and provisions up from Andai did not succeed. In consequence of a quarrel between the Arfaks and the people of Dorey, in which one of the natives was killed, his friendly intercourse began to be interrupted. Neither women nor children brought him insects, and soon afterwards they refused to sell him yams and maize. The Corono informed him, through the interpreter, that they were expecting an attack at Atam, and intended to leave the village. This D'Albertis did not believe until they commenced destroying the plantations, when his position becoming critical from want of provisions, he arranged with the Corono to return to Andai at the end of the month.

On September 29, accordingly, D'Albertis left Atam at sunrise, accompanied by about forty persons, his health having been much improved by his sojourn in the mountain air. Returning by a shorter route, he avoided Putat, and on arriving, on October 1, at Andai, found, to his regret, that Signor Beccari had gone on to the former village, so that if he had passed through it he could have obtained a fresh supply of provisions.

During his month's residence at Atam, Signor D'Albertis obtained 122 specimens of birds, and a large collection of insects, besides some mammals and other specimens. The only part of these that have yet reached Europe is the series of birds, of which an account was given in a previous number of NATURE (vol. viii. p. 305). The mammals obtained are stated to embrace several species of *Cuscus*, one of which is believed to be new, two or three species of Tree-kangaroo (*Dendrolagus*), a *Pteropus*, a Squirrel, and several species of Mice and Bats. The Insect collection is rich in *Cetoniæ* and *Melolonthæ*.

Soon after his month's excursion to the Arfak mountains, Signor D'Albertis was compelled, by continued attacks of fever, to leave New Guinea and proceed to Sydney, in the Italian frigate *Vettore Pisano*. Dr. Bennett informs me that his health is now re-established, and that he will probably return to Europe in a few months.

This interesting narrative serves to show us that the dangers and difficulties of penetrating into the interior of New Guinea, though considerable, have been somewhat over-rated. Though Signor D'Albertis has been the first to publish an account of his adventures in this country, I believe that the naturalist Rosenberg, in the employment of the Leyden Museum, had already made an expedition into nearly the same district.* Where these two pioneers have found their way, others will doubtless

* Several of the new birds described by Dr. Schlegel, in his article on Rosenberg's collections (*Ned. Tigdschr.* iv p. 33), were also obtained by D'Albertis, but the only locality assigned to them is "l'intérieur de la grande presq'ile septentrionale de la Nouvelle-Guinée."

quickly follow, and we may thus hope to acquire, before long, a complete knowledge of one of the most wonderful floras and faunas of the world's surface.

P. L. S.

THE MOTION OF PROJECTILES

A Mathematical Treatise on the Motion of Projectiles, founded chiefly on the results of Experiments made with the author's Chronograph. By Francis Bashforth, B.D., Professor of applied Mathematics to the advanced class of Royal Artillery Officers, Woolwich, and late Fellow of St. John's College, Cambridge. (London: Asher and Co., 1873.)

WE are told in the Preface to this work that "the consideration of the motion of a projectile naturally divides itself into three parts—first, its motion in the bore of the gun; second, its motion through the air; and third, its motion during its penetration into a solid substance." The author directs his attention chiefly to the second of these parts. Galileo was the first person who determined with anything like accuracy the motion of a solid body moving through space under the action of gravity. Treating the vertical and horizontal motions as perfectly independent (which of course is in accordance with Newton's laws of motion), he showed that a particle moved in a parabola. In this theoretical investigation gravity is supposed to be constant, and to act in parallel directions, while the effect of the resistance of the air is totally disregarded. The parabolic motion is approximately true for bodies whose velocities are small, but the greater the velocity of a projectile, the more does its path deviate from a parabola, and, in the present days of large guns and heavy charges, we can at once see the importance of solving with the greatest possible accuracy the problem of the motion of a projectile through the air, considering the air as a resisting medium materially affecting the motion of the shot. Newton solved the problem of the motion of a body through a medium whose resistance varies as the first power of the velocity, and John Bernoulli extended it to the case of resistance varying as any power of the velocity.

Experiments, however, show that the resistance cannot be regarded as varying as any single power of the velocity, though, within certain limits, the third power gives pretty accurate results.

Mr. Bashforth has applied himself to the task of throwing Bernoulli's solution into a practical shape, so that by means of copious tables, of which his book contains more than 100 pages, such problems as the following may be solved:—"The 16-pounder muzzle-loading gun fires an ogival-headed shot 16 lb. in weight, and 3·54 inches in diameter. If the angle of projection be 2°, and the initial velocity 1,358 feet per second, find the trajectory and time of flight." "A Rodman shot weighing 452 lb. is fired with an initial velocity of 1,400 feet per second, at a target 500 yards off, find the striking velocity."

Experiments were made by Robins and Rumford last century to ascertain the pressure of fired gunpowder and several persons have attacked the problem during the present century. General Mayevski attempted to solve the problem by firing shot, into the back of which a rod was screwed, the rod running through an aperture in the breech of the gun, and carrying a knife edge which cut two thin wires at a given distance, the interval of time between the two breakages being measured as accurately as possible. Captain Rodman made use of the following arrangement:—A gun was mounted in a gun-pendulum, and a revolving cylinder was placed with its axis parallel to that of the gun. When the gun was fired, a tracing point on the gun drew a curve on the revolving cylinder, the shape of which curve determined the whole motion of the gun's recoil. Mr. Bashforth suggested that much greater exactness would be procured if the tracing-point were connected with the projectile. He managed to do this to some extent by firing a shot through a number of equi-distant vertical screens, made of very thin metal wires. By an ingenious arrangement, the time of the shot breaking a wire in each screen was registered by means of an electric current on a revolving cylinder, special care being taken that all the registrations should be made under the same circumstances, so as to eliminate what we might call the personal error on the different registrations. This gave the times of transit of the shot over the successive intervals between the screens: from them, the velocities at the different screens can be calculated with great exactness, and also the resistance of the air on the shot. Mr. Bashforth has made great numbers of experiments with shots of different shapes and sizes, fired with different charges of powder, and from them has with great labour calculated the tables above referred to, which are sufficient for the solution of the problems we have given above as examples of what Mr. Bashforth has been able to accomplish.

The work is one which is too mathematical to do full justice to in our columns, but we have no hesitation in recommending it to such artillerists as are not unacquainted with mathematical analysis.

OUR BOOK SHELF

Half-hours with the Microscope. By E. Lankester, M.D. (Hardwicke.)

THIS excellent and well-known little work would scarcely require to have special attention now drawn to it, if it were not that the present edition contains an additional chapter, which adds much to its value as a text-book for amateurs. Until now the subject of polarised light has been omitted, and as the many beautiful and striking results which can be obtained by its employment are among the most important and attractive in the whole field of microscopy, any work on the subject in which it is omitted must be necessarily incomplete. The author, evidently feeling this, has added a "Half-hour with Polarised Light," which he has entrusted to the hand of Mr. F. Kitton, who, in the short space allowed him, has explained the theory of this rather intricate subject in a clear and popular manner, and has described some of the most striking of the phenomena exemplified by it, such as the appearance of the slides of iodo-sulphate of quinine, asparagine and sulphate of copper in gelatin, together with the methods for arriving at them. The addition of this chapter has made this work as complete as it is useful to the commencing microscopist.

Proceedings of the Belfast Natural History and Philosophical Society. (Belfast, 1873.)

WE welcome with pleasure the first number of the Belfast Society's Proceedings, which includes a number of papers

read during the session 1871-2, some of which are already known to our readers. We need only name the principal papers. There is, first, the Presidential Address of 1871, "On Motive Power," delivered by Mr. J. J. Murphy, who has also a short paper on "The Bernina Lakes;" then comes Prof. James Thomson's admirable paper, "Speculations on the Continuity of the Fluid State of Matter, and on Transitions between the Gaseous, the Liquid, and the Solid States." This is followed by two short papers, one by Dr. J. D. Everett on "The Reduction of Observations of Wet and Dry Bulb Thermometers," and another on "Recent Changes of Coast-level at Ballyholme Bay, Co. Down," by Mr. Robert Young, C.E., who has also an excellent paper on "The Duty of Preserving National Monuments." Mr. John Anderson contributes a paper on "The Geological Formation of County Down," the Rev. Dr. Macloskie a long paper on "The Silicified Wood of Lough Neagh;" and there are also one or two papers of antiquarian and social interest. Appended is an interesting obituary notice by the secretary, Mr. Taylor, of the late Mr. Robert Patterson, F.R.S., one of the founders of the Society, and who, amid the cares attendant on the carrying on of a large commercial establishment, managed to find time to prosecute to very good purpose the study of natural history, and even to write admirable zoological text-books, and take an active part in the promotion of science and of social progress. The first number is edited by Mr. Murphy and Dr. H. Burden, and we hope the Society will produce material enough to bring out an equally good number every year.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

Dr. Huizinga's Experiments

In a letter published in last week's NATURE, in which Dr. Bastian comments on a short paper read by me at Bradford on certain experiments of Dr. Huizinga, he challenges me to deal with his "main proposition," which is "that Bacteria are capable of arising in fluids independently of living reproductive or germinal particles."

In so far as relates to the subject of my communication, I have done so by showing that in the case of Huizinga's liquid Bacteria can be prevented from arising by heating the liquid to a temperature somewhat above boiling.

I hope that Dr. Bastian will allow me to decline to enter on the general question, and will believe that in doing so I am not insensible either to the difficulties of the subject, or to the value and importance of his own experimental investigations.

Oct. 13 J. BURDON SANDERSON

Experiments on the Development of Bacteria in Organic Infusions

THE correspondence in your journal on this subject (relating chiefly to the statements of Dr. Bastian) in which I took a part some six or seven months since—renders it necessary, in justice to myself, and I may add, in justice to the memory of my friend, Dr. Pode, whose loss has prevented me from continuing a series of experiments on the nutrition of Bacteria, commenced in the spring—to give some account in your columns of experiments carried out by us, which demonstrate that Dr. Bastian's assertions as to infusions of turnip and turnip-cheese are devoid of foundation in fact. The paper in which our results are given in detail was sent in to the Royal Society at the end of last March and printed in May (Proceedings, No. 145). Since you are not able to afford space for the reproduction of that paper in full, I must beg to refer your readers, for details, to that publication of the Royal Society. Here I may be allowed to sketch briefly the results and their bearing on Dr. Bastian's statements. The following passage from that gentleman's "Beginnings of Life" (vol. i. p. 429) induced us to make experiments similar to those mentioned in it, with the view of testing the correctness of his conclusion as to matter of fact:—

"On the other hand, the labours of very many experimenters have now placed it beyond all question of doubt or cavil that living *Bacteria*, *Torulæ*, and other low forms of life will make their appearance and multiply within hermetically-sealed flasks (containing organic infusions) which had been previously heated to 212° F., even for one or two hours. This result is now so easily and surely obtainable, as to make it come within the domain of natural law." And in a note is added, "in a very large number of trials I have never had a single failure when an infusion of turnip has been employed; and from what I have more recently seen of the effects produced by the addition of a very minute fragment of cheese to such an infusion (see Appendix C, pp. xxxiv.-xxxviii), I fully believe that in 999 cases out of 1,000, if not in every case, a positive result could be obtained."

The extract which follows is from a paper by Dr. Bastian in NATURE, vol. vii. p. 275, and is perhaps more remarkable than the preceding, because it is of later date and refers to a simple infusion of turnip.

"Taking such a fluid, therefore, in the form of a strong filtered infusion of turnip, we may place it after ebullition in a superheated flask, with the assurance that it contains no living organisms. Having ascertained also, by our previous experiments with the boiled saline fluids, that there is no danger of infection by *Bacteria* from the atmosphere, we may leave the rather narrow mouth of the flask open, as we did in these experiments. But when this is done, the previously clear turnip-infusion *invariably* becomes turbid in one or two days (the temperature being about 70° F.), owing to the presence of myriads of *Bacteria.*" The italics are my own.

Dr. Pode and I give in our paper the details of 53 experiments, of which 11 were made with hay-infusion, the rest with turnip- or turnip-and-cheese infusion. We had some trouble at first in ascertaining some of the conditions under which Dr. Bastian experimented—since he does not state them in his book. In the first place we ascertained through these columns the specific gravity of Dr. Bastian's turnip-infusion. We made a number of experiments after obtaining that information, which are recorded in our paper, and which invariably gave opposite results to those obtained by Dr. Bastian. At the beginning of this year we ascertained through Dr. Sanderson, in the columns of NATURE, that Dr. Bastian made use of two-ounce retorts; and that particles of cheese visible to the naked eye were present in his infusions at the time of boiling. Dr. Sanderson also stated that Dr. Bastian attached importance to the peeling of the turnips used. With this additional information we made further experiments, which tend to explain the failure of Dr. Bastian to keep his infusions free from Bacterian contamination.

There are four points which require attention in these experiments, and which were attended to in our series, but we must suppose were not attended to by Dr. Bastian.

In the first place the infusions were examined by the microscope at the time of sealing the tubes, as well as subsequently. What we sought to determine was whether a change had occurred in the infusion. Spherical and other particles besides dead Bacteria occur in freshly-boiled infusions, which might lead to erroneous conclusions when seen subsequently, if their previous existence had not been ascertained.

Secondly, we employed small tubes, five inches in length and of half-inch bore. It appeared to us not at all improbable, from the results of some experiments made by us with retorts such as Dr. Bastian used, that a boiling for five or ten minutes, before closure, of an ounce of liquid in a vessel of that peculiar shape, might sometimes give a development of Bacteria, owing to the protective effect of "spluttering," and the large mass to be guarded.

Thirdly, in the majority of cases—though we had no reason to doubt the efficiency (as proved by the results) of the boiling for five minutes in one of our small tubes, *ceteris paribus*—yet, to ensure thorough exposure of every part of the tube and liquid to the boiling temperature, we submerged many of our tubes in boiling water for a quarter or a half an hour after their closure. This method we finally adopted as the most certain to ensure the destruction of Bacterian contamination; it is essentially the same as that subsequently adopted by Dr. Burdon-Sanderson in the experiments described in a letter in NATURE, vol. viii. p. 141, the difference being that, "to make assurance doubly sure," Dr. Sanderson raises the temperature of the water in which his tubes

are submerged above 100 C. by increasing the pressure under which ebullition is effected, beyond the normal atmospheric limit.

A fourth point to which we gave attention was the possible preservative effect of "lumps" on Bacteria or their germs. No one would have supposed that Dr. Bastian neglected the precaution of removing large particles of cheese from his experimental infusion. We always strained our cheese emulsion very carefully, or else filtered it. Prof. Cohn found that an infusion made by boiling a pea in water developed Bacteria when the pea was left in it; but if the pea were removed, and the infusion subsequently reboiled, no Bacteria were developed. We found that lumps of cheese could really act as protective hiding-places for Bacterian contamination. In a retort—similar in every respect to Dr. Bastian's—this result was first obtained, though other retorts similarly treated were barren. Accordingly we prepared twelve tubes exactly alike, with the exception that in six the cheese was added as an emulsion, in the other six in the form of lumps. The tubes were closed, and submerged in boiling water for five minutes. Of the "emulsion"-tubes, one burst in the boiling, the other five were barren; of the "lumpy"-tubes, four developed Bacteria in quantity, two remained barren.

In the experiments recorded in NATURE, vol. viii. p. 141, by Dr. Sanderson, it is shown that even when "lumps" are avoided, and the infusion heated by submergence in boiling water, this may not prevent the development of Bacteria when a large bulk of material is employed. But boiling for such a length of time as one hour, or heating to 101° C., always gave him a barren infusion. Dr. Sanderson does not believe that there is a definite relation between the precise temperature to which the infusion is exposed and the destruction of Bacterian contamination, but that the *longer* heating, or the heating to a *higher* degree, will increase the *chance* that Bacteria or their germs are destroyed. Further, Dr. Sanderson's results agree with those of Dr. Pode and myself as to simple turnip infusion. With this infusion I understand that he has not found the same length or amount of heating necessary as with the turnip infusion to which a fragment of cheese has been added.

And now, I wish very briefly to point out where Dr. Bastian's statements are affected by these results. It is necessary that this should be clearly and simply put, because I find that many persons are under the impression that the investigation of the grounds of Dr. Bastian's statements has shown that there was some solid foundation for them. This is, however, in my opinion, not the case. It is *not* "beyond all question of doubt or cavil that living Bacteria, Torulæ, and other low forms of life will make their appearance and multiply within hermetically-sealed flasks (containing organic infusions) which had been previously heated to 212° F. even for one or two hours." On the contrary, no organic nor inorganic infusion has been contrived by Dr. Bastian nor by anyone else which will develop Bacteria, still less Torulæ, after exposure for one hour (or even less) to 212° F. This is the conclusion given by the impartial examination of the subject, indicated in the experiments above quoted.

Moreover, the statement in the second quotation from Dr. Bastian is abundantly contradicted by the experience of Dr. Sanderson, Dr. Pode, and myself. Such a turnip-infusion, placed as directed by Dr. Bastian, does *not* invariably become turbid in one or two days, owing to the presence of myriads of Bacteria. We have often kept such infusions free from Bacteria for many days, and I preserved one in a retort with its beak inclined downwards for more than six months, clear as crystal, but amply capable of sustaining the life of Bacteria, as was proved by its accidental contamination a week ago.

It is my opinion that the only *positive* addition to knowledge which this inquiry about the development of Bacteria in infusions has led to is, that when you have cheese-emulsion, or similar material present in an infusion, you must be a little more careful about heating it than when you have not, if you wish to destroy by the agency of heat the life of Bacteria or their germs contained in the infusion. How it is that cheese-emulsion helps the Bacterian contamination to escape destruction we do not know. Possibly in the same way as the larger lumps do. But that matter remains for inquiry when more is ascertained as to the natural history of the Bacteria. I think we may now feel fully satisfied that "archebiosis" or "abiogenesis" is not in any way rendered more probable than it was before by Dr. Bastian's experiments with organic infusions. Prof. Smith and Mr. Archer, of Dublin—eminent authorities in the study of the lower algæ—have criticised in detail and suggested explanations of some of the statements in the third part of "The Beginnings of Life," viz., statements relating to the transformation of various species of organisms into others. They show (the reader may consult Prof. Smith's paper in the October number of the *Quarterly Journal of Microscopical Science*, 1873) that the asserted "facts" of transmutations are *not* facts. It is abundantly demonstrated that the fundamental observations recorded by Dr. Bastian are erroneous, and that he has been mistaken.

Exeter College, Oxford, Sept. 26 E. RAY LANKESTER

Variations of Organs

MY father finds that in his letter, published in your number for September 25, he did not give with sufficient clearness his hypothetical explanation of how useless organs might diminish, and ultimately disappear. I therefore now send you, with his approval, the following further explanation of his meaning.

If one were to draw a vertical line on a wall, and were to measure the heights of several thousand men of the same race against this line, recording the height of each by driving in a pin, the pins would be densely clustered about a certain height, and the density of their distribution would diminish above and below. Quetelet experimentally verified that the density of the pins at any distance above the centre of the cluster was equal to that at a like distance below; he also found that the law of diminution of density on receding from the cluster was given by a certain mathematical expression, to which, however, I need here make no further reference. A similar law obtains, with reference to the circumference of the chest; and one may assume, with some confidence, that under normal conditions, the variation of any organ in the same species may be symmetrically grouped about a centre of greatest density, as above explained.

In what follows I shall, for the sake of brevity, speak of the horns of cattle, but it will be understood that my father considers a like argument as applicable to the variations of any organs of any species in size, weight, colour, capacity for performing a function, &c.

Supposing then that a race of cattle becomes exposed to unfavourable conditions, my father's hypothesis is that, whilst the larger proportion of the cattle have their horns developed in the same degree as though they had enjoyed favourable conditions, the remainder have their horns somewhat stunted. Now, if we had made a record of the length of horn in the same species under favourable conditions, we should, as in the case of the heights of men, have a central cluster, with a symmetrical distribution of the pins above and below the cluster. According to the hypothesis, the effect of the poor conditions may be represented by the removal of a certain proportion of the pins, taken at hazard, to places lower down, whilst the rest remain *in statû quo*. By this process the central cluster will be slightly displaced downwards, since its upper edge will be made slightly less dense, whilst its lower edge will become denser; and further, the density of distribution will diminish more rapidly above than below the new central cluster.

Now, if horns are useful organs, the cattle with shorter horns will be partially weeded out by natural selection, and will leave fewer offspring; and after many generations of the new conditions, the symmetry of distribution of the pins will be restored by the weeding out of some of those below the cluster, the central cluster itself remaining undisturbed.

If, on the other hand, horns are useless organs, the cattle with stunted horns have as good a chance of leaving offspring (who will inherit their peculiarity) as their long-horned brothers. Thus, after many generations under the poor conditions, with continual intercrossing of all the members, the symmetry of distribution will be again restored, but it will have come about through the general removal of *all* the pins downwards, and this will of course have shifted the central cluster.

If, then, the poor conditions produce a *continuous* tendency to a stunting of the nature above described, there will be two operations going on side by side—the one ever destroying the symmetry of distribution, and the other ever restoring it through the shifting of the cluster downwards.

Thus, supposing the hypothesis to be supported by facts (and my father intends to put this to the test of experiment next summer), there is a tendency for useless organs to diminish and finally disappear, besides those arising from disuse and the economy of nutrition.

Down, Beckenham, Oct. 4 GEORGE H. DARWIN

Oxford Physical Science Fellowships

I WRITE this letter that in future candidates for Oxford Fellowships in Physical Science may be aware that outsiders are ineligible.

In June last the Warden of Merton College informed me that the election to a Physics Fellowship would *not* be limited to graduates of Oxford, and would altogether depend on the result of the examination held at Merton on Oct. 7. Candidates had no other information than was afforded by the notice in your columns.

Although I found that great difficulties were thrown in the way of outsiders in their not being allowed an opportunity of examining the physical apparatus which was to be used in the examination, and with which Oxford men are well acquainted, I read for the examination, not having the slightest doubt about my eligibility after receiving the Warden's letter.

It is now nearly four months since I received the letter, and although the authorities must have been very well aware of the grave error which had been fallen into, I was not informed that a blunder had been committed until the morning of the examination. It is now found by the Warden, on consulting the registrar of the university, that only Oxford graduates can compete for these Fellowships.

Oxford, Oct. 8 JOHN PERRY

Simple Method of Studying Wave Motion

IT is difficult for a student to obtain a clear idea of the movement of the particles of a liquid or gas propagating a wave. To assist him models have been devised, but as a rule they are expensive and complicated. The following plan, based on the principle of the stroboscope, I have found extremely convenient. Take a piece of cardboard about 3 ft. long and 18 in. broad. Put this into the tin drum of a "zoetrope," pressing the card well against the interior of the drum, so that it stands up forming a cardboard cylinder. With a lead pencil mark where the inside fold of card comes, and you have the right size of the cardboard to form the cylinder. Divide now the length of the cardboard into 12 equal strips. On each strip paint dots representing the wave you want to study, taking care that each wave is represented $\frac{1}{12}$ behind its predecessor. Lastly, cut out 12 slits, about 8 in. by $\frac{1}{4}$ in., between each representation of the wave; restore the card to the drum of the zoetrope, and then turning the cylinder and observing through the slits, the wave is seen, as the cylinder revolves, to advance with its characteristic motion, while by stopping out all but one of the particles represented the exact character of its oscillation, whether circular, elliptical, or linear, is clearly seen.

Midland Institute, Birmingham C. J. WOODWARD

The Glacial Period

JUST one line in reply to Frank E. Nipher. I have read Tyndall's Lectures on Heat, and that some time before I addressed you on the subject of the Glacial Period. Plainly, it is against common sense to suppose that an increased outpour of solar energy would diminish the mean temperature of the air at the earth's surface to such an extent that glaciers at or near sea level should be found in Egypt, or even, I believe, in Central Hindustan, as was the case in the Glacial Period. All I can say is, that if the sun then were a hotter sun than the sun of our own age, he must have blundered at his work.

And now may I crave space for just another line on another subject? Could not our learned societies be induced to publish their mathematical contributions separately? I was compelled to take the whole of the first part of the Royal Society's Transactions of 1867, for the sake of Clerk-Maxwell's paper on Molecules. For this I paid a guinea—willingly, indeed; but had the paper been published alone, I should probably have had it for a much lower figure. Then there are Professor Stokes' and Sir W. Thomson's magnificent papers scattered up and down among the Transactions of the Royal and Cambridge Philosophical Societies; if these were gathered together and published apart, it would be a precious boon to persons like myself who are interested in physical mathematics. And pupils of the Ecole Invariantive would, no doubt, be as much gratified by an easier access to the numerous contributions of Professor Cayley to the Theory of Determinants. Is it impossible, or even inconvenient, to afford such facilities to students and amateurs?

Hampstead, N.W., Oct 3 J. H. RÖHRS

THE OWENS COLLEGE, MANCHESTER

IT is now upwards of twenty-two years since this college was opened—for the foundation of which in Manchester, John Owens, a merchant of that city, left 100,000*l.*—in a house that belonged to Mr. Cobden, in Quay Street, which was purchased and presented to the trustees by Mr. John Faulkner, the first chairman. The number of students during the first session was 64, which went on increasing year by year, until last session the day students numbered 327, and the evening students 513. A few years ago it was felt that the original house had become much too small, and that a new building ought to be erected adequate to the increased needs of the College. Accordingly, in 1866, a circular was prepared, setting forth the disadvantages of the then institution, and propounding an extension scheme which should include the additions to the College of a school of Engineering, a Medical School, and the Natural History Museum, which the Council of the Natural History Society recommended should be deposited in Owens College, "if it should appear that the scheme for enlargement was likely to be successfully carried out within a reasonable period." The trustees therefore appealed for funds which would enable them to lay the foundations of an institution which would virtually be the University of South Lancashire, and of the neighbouring parts of Cheshire and Yorkshire.

In 1867 an Extension Committee was formed for raising a fund, which "it was desirable should not be less than 100,000*l.*, and, if possible, 150,000*l.*," to carry into effect the proposed system of extension. 24,000*l.* was almost immediately subscribed. The engineers of Manchester and neighbourhood subscribed 10,000*l.* to found and endow a chair of Engineering Science, and for the provision of an apparatus and a library. An application to the Government for a grant, though never absolutely refused, was first temporarily shelved on the familiar plea that the subject was "under consideration," and on a change of Government it was ultimately forgotten. The success of the College is therefore a monument of voluntary effort. After the present site had been purchased, the sum of 12,000*l.* was subscribed towards the new Medical School. Principal Greenwood and Prof. Roscoe subsequently visited Germany, and obtained valuable information as to the schools of science in that country; and to the plans which the Professor of Chemistry especially brought home, the new College owes the perfect arrangements in its scientific lecture-rooms, and the handsomely fitted-up laboratories for chemical and physiological science; laboratories, we believe, which are not equalled by any in the kingdom, if, indeed, in Europe.

The foundation-stone of the buildings just completed was laid by the Duke of Devonshire in September 1870, and the same nobleman occupied the chair at the opening of the new building on the 7th instant.

As is well known, the "religious difficulty" has been entirely obviated, in the case of Owens College, by the will of the founder, which requires "that the students, professors, teachers, and other officers and persons connected with the said institution, shall not be required to make any declaration as to, or submit to any test whatsoever of, their religious opinions," and that "nothing shall be introduced into the matter or mode of education or instruction, in reference to any religious or theological subject, which shall be reasonably offensive to the conscience of any student, or of his relations, guardians, or friends under whose immediate care he shall be." It is no doubt partly owing to this that the Manchester

College can boast a body of teachers not surpassed in any respect by any university in the kingdom.

The college is rich in scholarships, fellowships, and prizes founded by Manchester men, and by means of these, and its admirable system of day and evening classes, affords facilities to all classes of obtaining a literary and scientific education, both general and professional, of the highest and most advanced kind. In most respects, indeed, it may be regarded as a model institution for the higher education.

Of the many excellent addresses given on the occasion, we have only space for a few extracts from those of Principal Greenwood and Sir Benjamin Brodie. We shall take another opportunity of referring to the address of Prof. Roscoe at the opening of the Chemical School.

Principal Greenwood said:—"I am addressing the assembled students of the new year; and it is because I feel that you are even more concerned in the inquiry than are my colleagues and myself that I ask you to consider some of the relations which subsist between culture and practical life, not as matters of speculative interest, but as bearing closely on the aims and the temper with which you should take up the studies of this place. This inquiry might take either of two directions, according as we consider the debt due from society to the student, or the debt due from the student to society. It is not possible altogether to separate these inquiries; but it is of the latter that I propose to speak more especially this morning, not only because in addressing students, as in addressing other men, it is more wholesome to speak of their obligations than of their claims, but also because in this place and on this day, there is little need to urge the duties of society to the student.

". . . . For us the normal principles of education, in their whole range and mutual bearings, are of infinitely greater weight than the special questions which fix attention at the moment; but our thoughts are in danger of being drawn away from these deeper truths, and our springs of action of being in that degree weakened or perverted. An illustration of this position may be seen in the history of the vigorous and successful efforts which, within a few years, have been made in favour of the claims of the natural sciences to a leading place in the curriculum of study. Men of genius and of public spirit have insisted on them with unanswerable arguments; and I shall not be suspected by those who happen to be cognizant of the part which Owens College has taken in this matter with any inclination to call these claims in question. I wish, however, to point out that arguments are urged in their support of very unequal force; and that while the able leaders of the crusade dwell most on the stronger among them, their followers are wont to recur too frequently to the weaker, and by raising them into undue prominence to run the risk of inducing—not the general public only, but what is in reality a more serious thing, of inducing you and us to hold pernicious views as to what education is and what are the appropriate motives for it. Of these arguments the weightiest is, I will venture to affirm, the most seldom heard. I mean the assertion that the natural and experimental sciences have a characteristic discipline for the mind. This position may in this place be taken for granted; and it constitutes of itself an argument at once unanswerable and sufficient. But when we hear the further argument that physical sciences should hold a prominent place in education because their promotion contributes to the material advancement of the country, or because to possess a knowledge of them will give the learner a greater command of money and what money brings, we are then offered motives of a very different order. As collateral motives they have great value, I admit, for exaggeration on one side must not be met by exaggeration on the other, but a value subordinate to that of the former consideration. It is, of course, true that all good education, through whatever medium, tends to produce good and well-furnished citizens, and therefore promotes the general, including the material, well-being of a country; and all good sound education tends to make men manly and self-reliant, and so trains their faculties as to enable them, among other things, to win with ease their share of material good. It is true too, that in choosing the subjects of study regard should be paid, in due degree, to the destination of the future life. But when the secondary and by nature inferior aim takes the first rank, the fatal consequence follows that the higher good is not even sought in the second place. The greater may include the less, but not the less the greater.

"Another instance of harm to the business of education from the passing controversies of the hour lies in the sudden development of the system of competitive examinations. To discuss the merits of this system in itself is altogether beside my object. I wish to refer only to its oblique influence on teachers and pupils, or rather (for each of these schemes would admit of long discussion) of its influence on the temper of the student. Can anything be more deplorable—if it were not deplorable it would be grotesque—than the change which this system threatens to bring about in the mutual relations of study and examination? By the old theory the business of education was—first, the discipline of the intellect by means of the arts and sciences as instruments; and, secondly, the storing of the mind with methodical knowledge gained in the process. Examinations were but the handmaid of the teaching, designed to test and measure the results of study, and so to correct its methods; and if honours and more substantial rewards were conferred on those who took the foremost places, this was partly to stimulate the flagging, and enable the more promising wits to prolong their season of study, and partly that public or academical offices might be filled by the fittest occupants. . . . Now, however, men are almost tempted to think that the public service exists for the sake of the sharp-witted or the industrious, and not they for it. 'La carrière ouverte aux talens,' once the stirring motto of an indignant people, has become a circumlocutory and more decorous version of the frank maxim of ancient Pistol—

'The world's mine oyster,
Which I with sword will open.'

". . . We are now prepared to answer the question which I wish to propose: What were the conditions under which for many centuries the theory of the higher education was this—that to all who sought it a common culture was provided in the first instance, and that from this, as from a trunk, three or four types of special or professional training branched off. And again, to what influences is it due that in the present day many are found to advocate the abandonment of this principle in favour of a method by which, the common groundwork being reduced to the narrowest limits, the special training is made to begin with the first years of college life or even at a still earlier date? One answer to this question (but not the only answer) I have already indicated, viz., that according to the older theory 'a complete and generous education,' in the words of Milton, was 'that which fits a man to perform justly, skilfully, and magnanimously all the offices, both private and public, of peace and war;' whilst the other theory holds that the aims and interests of the individual are to be chiefly kept in view. Now it is no doubt true that, as is sometimes urged, these rival theories may be so handled as in appearance to lead to the same result; but in appearance only. It is true that the highest development of any community not only allows, but requires, that the best possible should be made of each of its members; and it is not less true, if less obvious, that an enlightened selfishness might discover that in the long run it can serve itself best by serving others. But 'enlightened selfishness' has been a great many centuries

in learning, in this region as in others, how 'to save by losing itself.' If then, as of course no one will seriously question, the older theory be sound, it will not be safe to leave the course of study wholly to the caprice of individuals. The experience or instinct of academic bodies has aimed at giving effect to this principle by requiring that students aspiring to academic honours, and to those diplomas which are the passports to the so-called learned professions, should pursue a course of studies uniform, or nearly uniform, up to a certain defined point. In our day, when university training is no longer sought only by those who seek to enter the great professions, and when, too, the narrow list of these liberal professions is from time to time receiving one and another sister, it is a principal academic problem to show that the old principles ought still to be insisted on in their essence, and yet that modifications must be made in detail, in order that they may be applied with safety. It is when we have to meet the reluctance—the natural reluctance—of students of this new order to submit to the yoke of academic traditions that we are brought face to face with the rival claims of society and the individual. I say the rival claims; but, in fact, they are not rivals, but complementary each of the other. I mean not only that each has its rights, which must not be ignored, but that each is necessary to the perfect development of the other; that unless due play is given to the special gifts and aspirations of its members, society cannot reach its highest form; and that, unless individual men remember that they exist for the sake of society at least as much as for themselves, they too will fall short of their proper standard, and will leave some of their noblest faculties wholly unused. . . .

"... The subject matter of the studies selected is, in fact, of less importance than the discipline imparted. This only is essential—that there should be such a selection made as will (1) draw out and strengthen the several powers of the mind, and (2) afford a basis so broad that on it may afterwards be erected the structure of professional study when the career is chosen. These conditions are met if the common groundwork includes (1) letters, to cultivate the taste and judgment, to give a good style in speech or writing, and to place the student on the threshold of the best literature of home or foreign growth; (2) mathematics, to discipline the reasoning faculty, to give the habit of concentrated thought, and to place in the student's hand a weapon indispensable for the thorough mastery of the physical branches; and (3) some branch of physical study, to develop the powers of observation and inductive reasoning, and to impart the method of this study, so that, should the student afterwards take up a profession based on some physical science, as medicine, engineering, or manufacturing art, he may be able with facility and pleasure to provide himself with the technical knowledge proper to his calling. It might be added, too, in defence of the claims of this third prime element of culture, that it is singularly fitted to counteract the faults alleged, not without reason, to be inherent in the other two. But I must not proceed further on this field. I have placed the justification of the adoption of a common groundwork of culture for all students on two direct and, as I believe, sufficient pleas. But, over and above these direct uses, there are at least two others, which I can only indicate; —(1) Grace and vigour are lent to social intercourse when men feel that they can trust to the possession by all of a certain general culture—that a common atmosphere, so to say, is shared by all, and that subtle criticisms, delicate shades of thought, apt illustrations, will not fall flat on the ears of one half of those who listen. Those who are familiar with the social history of the first half of this century will agree with me that this element of social life was far more generally present with cultivated men than it is now. (2) And, again, from the want of this common elementary culture, men are without that sympathy with the pursuits of others which tends so powerfully to soften the bitterness of controversy, and even to make fruitful discussion possible."

Sir Benjamin Brodie's speech is specially remarkable as giving the impression which a long connection with one of the older Universities has made upon a distinguished man, whose sympathies would naturally be with them. We have only space for the following extract:—

"The foundation of such universities as Oxford and Cambridge is lost in almost prehistoric time; and if I say that this is the foundation of an university, I say so from what appears to me to be a very good reason, for I believe that Owens College boasts all the essential constituents of an university; and I have no doubt that before long it will go forth into the world equipped as an university in every respect. I know that some persons take a very different view of universities from that which I do. Some consider that the university is merely a sort of better grammar-school, which differs from the ordinary grammar-school by having more and older students, and a somewhat wider range of study. I don't believe that any enlargement of the curriculum of a grammar-school will ever elevate it into an university. Some persons consider that an university is a body which grants degrees. I confess that the granting of degrees is an important and responsible function; yet of all the functions of an university it appears to me the very least. To claim that function as the distinguishing characteristic of an university is equivalent to saying that the man who puts a stamp on a sovereign is the maker of the coin. An university should not only be a teaching body, but from every point of view it should represent, further, and promote the interest of knowledge, not only by teaching, but by preserving knowledge through the foundation of libraries, museums, and collections, and by the labours of its professors in furthering and increasing knowledge. I fully believe that that was the idea which was present to those who were concerned in the foundation of Owens College—namely, that it is to be not merely a grammar-school, but a great organ for furthering knowledge. . . .

"We have heard many allusions to-day to the financial condition of Owens College, and I do not doubt that there are many here who, in considering this question, look perhaps, I will not say, with some degree of envy, but with a peculiar interest, upon the statistics relating to the pecuniary affairs of Oxford and Cambridge. These great universities differ from Owens College as *plus* differs from *minus*. These institutions—Oxford and Cambridge—are in that happy position that their Chancellors of the Exchequer have no taxes to raise, and have only to consider the appropriate mode of distributing their budgets. But yet, really, any envy which might be raised from this consideration might be entirely removed by a more close intimacy and acquaintance with the subject, for though undoubtedly money is a good thing, and money well used is better than money itself, yet in many cases these endowments of universities have been so connected and linked with inappropriate objects, that they have really done more harm than good. The question of University Reform has been debated for about 30 years without the end being gained as to how to distribute these revenues properly. These revenues are also inappropriate and sometimes mischievous, doing great evil to the old universities in consequence of their application to objects which, though appropriate 300 or 400 years ago, are now useless, or worse. Unhappily these objects do not coincide with those which deserve attention at the present day, and the consequence is that a great amount of time and a large amount of energy and talent have been wasted in removing evils which have grown up in connection with these endowments. I hope that this kind of work will never be necessary in connection with the University of Owens, and I think you may congratulate yourselves that you have to begin *de novo*, and that you have only to adapt your arrangements to the purposes

you desire to be served. That is a much simpler thing to do than to adapt antique arrangements to purposes which they were not intended to serve. Another point in which there are some difficulties that the old universities have had to contend with comes before us in regard to those unfortunate arrangements which for so long a period connected them with a very unpopular party in the State. It is only recently that, by a prolonged series of efforts on the part of individuals, we gained the abolition of what were commonly termed university tests. I do not think I shall offend anybody by referring to that subject, because these tests may now be regarded with a curious, though somewhat painful, interest, like the thumbscrews and other instruments of torture of which we read in history; but in reality they constituted a very atrocious evil. We must all regret that they ever existed, not only on account of the labour and difficulty which they involved to those who took an active part in sweeping them out of the way, but also on account of the far worse amount of evil, in the shape of immorality and dishonesty, which they created. However, you at Owens College are happily free from all these evils. I earnestly hope, and fully believe indeed, that Owens College will ever preserve that union between freedom and science—freedom not only to think, but freedom of research and freedom of speech—which is absolutely necessary for the progress of science. I hope that nobody will ever meddle with your professors, and try to put an extinguisher upon their researches."

ON THE APPENDIX VERMIFORMIS AND THE EVOLUTION HYPOTHESIS

TOWARDS the close of the last meeting of the British Association at Bradford, a paper was read before the Biological Section, which calls for special comment, because of the unfavourable impression which it and much of the subsequent discussion must have left on non-scientific as well as scientific hearers, as well as on account of its scientific inaccuracy.

The paper referred to was by Prof. Struthers, who endeavoured to show that the appendix vermiformis of the human intestine may be considered as a good example of a useless and detrimental addition to the vital economy, and, such being the case, it must be apparent to all that evidence of design is not exhibited in the construction of the living body, and consequently the doctrine of special creation must be supplanted by that of evolution.

The general weakness of this argument must be apparent to many at first sight, but there are some points with reference to it which call for special remark. In the first place it may be shown, if it is assumed as true that the appendix vermiformis of the human cæcum is, as stated, useless and positively injurious, that the fact militates quite as much against the doctrine of the evolutionist, as it does against those of the teleological school. For if it is positively disadvantageous, on the Darwinian hypothesis, for the individuals of a species to possess an appendix vermiformis, it is a necessary deduction, that in a very short period either the species should die out, or be replaced by another in which the detrimental organ is absent. The human race and the anthropoid apes, however, seem quite able to hold their own, without the loss of their supplementary cæcum, consequently either the appendix vermiformis causes insignificant danger, or the evolution hypothesis is incorrect.

It is not difficult to demonstrate that it is the former of these two alternatives which fails, that the danger caused by the existence of the appendix vermiformis is much exaggerated, and that its uselessness is only an expression of ignorance on the part of those who make statements to that effect.

Some people have died from perforation of the appendix vermiformis, or the peritonitis which it induces; the number of recorded cases are comparatively few, and those which follow disease of the rudiment of the vitelline duct in the small intestine are much rarer, though Prof. Struthers seems to have seen several. This shows no doubt that there are disadvantages attending the possession of a complicated cæcum, or an unobliterated vitelline duct; but it shows too much for the argument on which we are considering its bearing, for there are many other organs, avowedly indispensable to the economy, which have caused death by their simple mechanical presence. A case was lately recorded before the Zoological Society, in which a kangaroo met its death from strangulation of a loop of the small intestine by the coiling round it of the uncomplicated, but long cæcum; are we from this to infer that the cæcum is so dangerous an addition to the organism, that it would be better if it did not exist? Such can hardly be correct. Again, in man, if the testes do not descend into the scrotum, impotency is the result, can we therefore infer that the abdominal rings would be better away, because some die of strangulated inguinal hernia? It would be as logical to wish to dispense with the head, because some have been killed by wounds on the scalp.

Again, it can scarcely be said in the present state of our physiological knowledge, that the appendix vermiformis is useless, and a remnant of a fœtal structure. Leaving sexual structures out of the question, as subject to different laws, it is quite contrary to evolutionary doctrine that useless rudiments of embryonic organs should be retained in after life; for the individuals encumbered with the unnecessary remains of a former different *régime* could scarcely be expected to succeed in the struggle for existence against less trammelled and consequently more advantageously circumstanced members of its own or any other class. If also the appendix vermiformis were a rudiment of a fœtal organ, it is not easy to see how it is that it is retained in man and the anthropoid apes, whilst it is not found in the lower monkeys, the Ungulata, and other animals which possess a cæcum (the wombat excepted), and are therefore similarly situated in early life. On the other hand, the voice of the evolution hypothesis clearly states that, with the exception above mentioned, the appendix vermiformis must bring positive advantage to its possessors; for it is only developed in the most elaborated and the highest of those creatures which are the result of its unceasing and most beautiful routine, and there is no reason why its action should cease at this point where it is most called for, and where the struggle is most acute.

There is another aspect in which we think the whole subject should be regarded. Prof. Struthers' remarks all have an anti-teleological tendency; in other words, they are little more than hits at a theory which has had its day, and which, if left alone, will die a quiet and natural death. Why make this death a painful one, and attempt to develop an unplesant party feeling between those who, from the capacities of their brains and their previous education, have been led to adopt the one or the other? Such discussions, as acknowledged by most who are competent to form a correct opinion, do very little, or nothing, towards the advancement of science, and tend to lower it very much in the estimation of the non-scientific world. The true theory will ultimately predominate, without doubt, but it will do so from its own intrinsic value, and not from attacks on the deepest feelings of its opponents, especially when they are based on a false interpretation of its deductions. To quote the words of one of the greatest of our physiologists, it can only bring ignominy on the body of scientific workers if they are supposed to countenance an argument such as that of Prof. Struthers, which assumes that because one or two individuals have died from the impactation of cherry-stones in the appendix vermiformis, therefore there is no God!

*THE COMMON FROG**

II.

BEFORE passing on to an enumeration of the subordinate groups of the sub-kingdom Vertebrata, we may first revert to our subject, the Frog, and make further acquaintance with it.

The common frog of this country belongs to the genus *Rana*, and it is the species *Temporaria*, therefore its scientific name is *Rana temporaria*. It is common in Ireland, as well as in England and Scotland, and is indeed the most widely distributed species of the frog-order, being found throughout the temperate regions of both the Old and New Worlds. It is found over nearly the whole of Europe; in Africa north of the Sahara, and in Egypt; in Northern Asia, including Japan and Chusan, and it is also spread over North America. It is not found in the northern half of Scandinavia, nor in Iceland.

Except in winter, the common frog is generally in England so familiar an object, that any description of it might seem superfluous. The purpose in view, however, renders it needful at least to recall certain external structural characters both of the adult and the immature condition.

The head and body of the frog together forms an elongated oval mass, somewhat pointed at each end, of which mass the head constitutes rather more than one-third. This mass is more or less flattened both above and below, except at the commencement of the hinder third of the back, where there is a more or less marked prominence, which indicates the junction of the haunch bones with the spine. In front of this the only marked projections are those of the eyeballs.

The short arms project outward on each side just behind the head, and each ends in a small hand with four fingers, the second of which is the shortest, and the third the longest. When the arm is turned backwards this third finger barely attains (if it can do so at all) the hinder end of the body.

The hind limbs proceed from quite the hinder end of the body, there being no vestige of a tail. The thigh is very muscular, and the leg has a good "calf." The foot is exceedingly long, and what is very remarkable, is so jointed that the toes can be sharply bent upwards on its thick and undivided part. The latter thus seems to form a third segment of the hind limb following the thigh and the leg, the limb having four segments instead of three as in ourselves, and in almost all beasts, birds, and reptiles.

The foot ends in five toes connected by a web. Of these the fourth is the longest, the first the shortest. On the inner margin of the sole of the foot, at the root of the first toe, is a small, hard prominence, called a "tarsal tubercle." When the hind limb is turned forward, the knee reaches nearly to the armpit; the ankle-joint is about on a line with the end of the snout, and both parts of the foot beyond it. These two parts of the foot together are much longer than the whole fore limb, and exceed two-thirds of the length of the whole mass of the head and body.

When the animal is viewed in profile, the point of the muzzle is seen to be very little in advance of the opening of the mouth. The latter is straight. It is also very wide, extending back even beyond the hinder margin of the eye. Just above the hinder angle of the gape, and behind the eye, is a rounded surface of smooth, tightly-stretched skin. This is called the "tympanum," and directly covers in the drum of the ear.

When the mouth is opened, if the finger be drawn along the inner margin of the upper jaw, a series of minute teeth may be detected. Towards the front of the palate are a pair of small holes (which are the inner openings of the nostrils), and between these are two juxtaposed little groups of other minute teeth. There are no teeth whatever in the lower jaw. At the hinder end of each side of the palate is another small hole. These latter two apertures are each the opening of a canal leading from the mouth to the cavity of the ear within the drum. The tongue is seen to be large, flat, and fleshy. It is tied down to the jaw in front, but free for more than its hinder half, with the processes developed from its free hinder margin.

The skin of the frog is naked and smooth, without a trace of scales, or other appendages. Its colour on the upper surface is more or less yellowish, or reddish brown, with irregular black, brown, or grey patches. Similar patches form transverse bands upon the legs. Beneath the colour is pale yellowish, often with a few spots, paler than those of the back. There is constantly a brownish black subtriangular patch placed behind the eye, and extending over the tympanum down towards the shoulder. The frog breathes partly by swallowing air (aided by a mechanism to be described hereafter), partly by the direct respiratory action of the skin. It feeds exclusively upon living animals, such as insects and slugs, which it catches by suddenly throwing forwards beyond the mouth, the free hinder half of the tongue (furnished with an adhesive secretion), and then retracting it with its prey in a most rapid manner.

* Continued from p. 471.

In winter the frog passes into that torpid state known as *hibernation*, as is the case with our bats, hedgehogs, and some other beasts. Its season of torpidity is generally passed by it buried in mud and at the bottom of water, and great numbers of individuals may be dug up in winter all clustered together.

In spring the frogs again congregate for the purpose of oviposition in the month of March, at which period their well-known croaking makes itself heard, and though in itself unmelodious, possesses a certain charm through its association with the vernal outburst of nature.

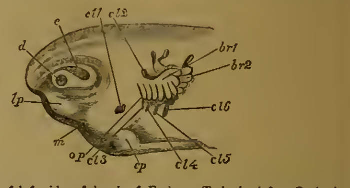

FIG. 3.—View of left side of head of Embryo Tadpole (after Parker). br^1 and br^2, first and second external branchiæ; cl^1—cl^5, the six viceral clefts; *cp*, the left "holder"; *d*, the olfactory organ; *e*, the eye; *lp*, th left lip; *m*, the aperture of the mouth; *op*, the hinder margin of the rudimentary operculum.

When first laid, the frog's eggs are little round dark bodies enclosed in no solid shell or case, but in a small glutinous envelope. The latter quickly swells in the water so much that the "spawn" comes to have the appearance of a great mass of jelly through which dark specks (the yolks of the egg) are scattered. Each egg, when microscopically examined, may be seen to undergo a process of yolk sub-division and cleavage till a mulberry-like mass is formed. Upon this soon appears the "primitive groove," which forms a canal and develops beneath it a "chorda dorsalis" according to the process which has been already stated to be common to the whole of the Vertebrata.

FIG. 4.—The Edible Frog (*Rana esculenta*).

Gradually the embryo assumes the form of a young tadpole, and is provided with a pair of little "holders" (or organs for

adhesion) just behind the mouth, with six openings on each side of the neck (Fig. 3, cl^1–cl^6), and with a pair of rudimentary external gills (Fig. 3, br^1 and br^2). These openings are termed "visceral clefts," which lead from the exterior into the throat, as already described. The solid pillars (or intervals) between the clefts, *i.e.*, the "visceral arches," become furnished with gills,* or *branchiæ*, and are therefore called "branchial arches." The eggs are hatched towards the end of April, and the tadpole emerges in the stage represented at Fig. 2, 1. It has a relatively large head, a rounded body, and a long tail, by lateral undulations of which the little creature swims about. From behind the head, on each side, jut forth external branchiæ as a small plume-like structure, but no limbs are visible.

As the tadpole grows the external plumose gills at first greatly enlarge (Fig. 2, 2 and 2*a*), but afterwards become gradually absorbed, and are succeeded by short gill-filaments, which are

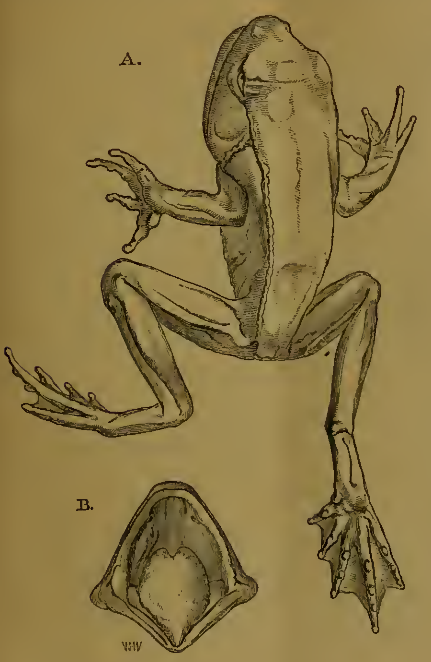

FIG. 5.—A, *Pachybatrachus robustus*, nat. size; B, interior of the mouth of ditto.

developed along each of the branchial arches. These latter filaments do not appear externally, and indeed a membrane, termed the operculum (Fig. 3, *op*), is developed from the front of each series of branchial apertures, and which, extending backwards by degrees, ultimately covers over and conceals them.

Little by little the limbs bud forth and grow, the hind ones being the first visible because the fore limbs are for a time concealed by the opercular membrane. As the legs grow, the tail becomes absorbed (Fig. 2, 7), not falling off, as some suppose. The gills also disappear, and the branchial apertures close, that on the right side first becoming obsolete by adherence of the operculum to the skin of the body.

As the gills diminish and cease to serve the purposes of respiration, lungs at the same time become developed in an inverse ratio, and the tadpoles absolutely require to come to the surface to breathe.

The process, from the hatching to the acquisition of the miniature form of the adult, may be accelerated or retarded by elevation or depression of the temperature. The frog more than doubles its bulk in its first summer.* The young tadpole has at first a very small mouth placed beneath the head and not at its anterior termination; it is also for a time provided with a sort of beak formed of two little horny jaws.

The food of the tadpole, quite unlike that of the adult, consists largely (especially in its earlier stages) of vegetable substances.

Having now made acquaintance with the Frog considered absolutely, or by itself, and also clearly seen that it is a member of the Vertebrate Sub-kingdom, we may enumerate the principal primary sub-divisions (Classes) of that Sub-kingdom, and enumerate such of the next smaller groups (Orders) as more or less nearly concern the subject of this work—the Frog.

The Vertebrata are divided into five great Classes:—(I), *Mammalia* (Man and Beasts); (II.), *Aves* (Birds); (III.), *Reptilia* (Reptiles, *i.e.* Crocodiles, Lizards, Serpents, and Tortoises); (IV.), *Batrachia* (Amphibians, *i.e.* Frogs, Toads, Efts, &c.); and (V.), *Pisces* (Fishes).

Of these five classes Birds and Reptiles are classed together in a larger group called *Sauropsida*, because they present so many structural resemblances. Similarly Amphibians and Fishes are grouped together, and to their united mass the common term *Ichthyopsida* is applied.

FIG. 6.—The Common Toad (*Bufo vulgaris*)

The orders into which the two classes, Mammalia and Aves (beasts and birds), are divided, may here be neglected, as we shall have little to say respecting them in the following pages. There are, however, about twelve orders of beasts, and probably some fourteen of birds.

The class of Fishes has been subdivided into five Orders.

1. Elasmobranchii (the sharks and rays, or highly organised cartilaginous fishes).

2. Ganoidei, an important order, containing many extinct forms, and a few very varied existing ones, such as the mud-fish (Lepidosiren), ceratodus, and the sturgeon.

3. Teleostei, the ordinary or bony fishes, such as the carp, sole, perch, &c., and containing a remarkable group called Siluroids, as also the curious little sea-horse—Hippocampus.

4. Marsipobranchii (the lamprey and myxine, or lowly organised cartilaginous fishes).

5. Pharyngobranchii (the amphioxus, or lancelet).

Reptiles are arranged in nine different orders, five of which are now entirely extinct. They are of living forms:—

1. Crocodilia (crocodiles).
2. Sauria (lizards, the Amphisbenæ, the little Flying-dragon, &c.)
3. Ophidia (serpents).
4. Chelonia (tortoises and turtles).

Of extinct kinds there are:—

5. Ichthyosauria; 6, Plesiosauria; 7, Dicynodontia; 8, Pterosauria; and 9, Dinosauria.

The remaining class, Batrachia, will require more lengthy consideration, both as a whole and as regards the four orders which compose it, and which are called respectively, 1, Anoura; 2, Urodela; 3, Ophiomorpha; and 4, Labyrinthodonta.

It will require such consideration, because it is the class to which the Frog itself belongs.

* Gills (or branchiæ) are delicate processes of skin richly supplied with minute blood-vessels, wherein the blood becomes exposed to the purifying action of the air dissolved in the water.

* Parker, Phil. Trans., 1871, p. 172.

The Frog belongs to the Batrachian order *Anoura*, to the family *Ranidæ*, and to the genus *Rana*.

The order Anoura, to which all frogs and toads belong, is a remarkably homogeneous one, consisting as it does of a multitude of species, all differing from each other by comparatively trifling characters.

Altogether there are about 600 species of frogs and toads, arranged in about 130 different genera.

St. George Mivart

(*To be continued.*)

*JEAN CHACORNAC**

THIS eminent French astronomer died on the 6th of last September, having been born at Lyon, June 21, 1823. Chacornac is chiefly known for his discoveries among the planetoids whose orbits are contained between those of Mars and Jupiter. In his earlier years he devoted himself to commerce, but having, in 1851, made the acquaintance of M. Valz, Director of the Marseilles Observatory, Chacornac became an enthusiastic student of astronomy, devoting himself to research in connection with the solar spots and to the assiduous exploration of the heavens. On his discovery of a new comet on May 15, 1852, he made up his mind to abandon commerce and devote himself entirely to astronomy.

In 1852, M. Valz, following the example of Mr. Hind, had drawn some charts of the region of the heavens in which the small planets were likely to be met with, and on Chacornac taking the above decision, Valz entrusted to him the construction of the "Atlas écliptique." Chacornac commenced his observations on the region of the small planets on June 1, 1852, and on September 20 he discovered Massalia, and on April 6, 1853, Phocæa, and that with an equatorial telescope of only thirteen centimetres aperture.

The poor resources which were at the disposal of the Marseilles Observatory did not permit of M. Valz's undertaking the publication of the ecliptic charts; and for this purpose he addressed the Academy of Sciences, which had appointed a commission to examine the question. M. Le Verrier, who at this time sought to reform the *personnel* of the Paris Observatory, called to his aid M. Chacornac, who, on March 4, 1854, was appointed Adjoint Astronomer.

At the Observatory of Paris, Chacornac had at his disposal an equatorial of 7 in. aperture, equal to that of Mr. Hind; he set down in his charts stars up to the 13th magnitude, and the limits which they embraced were at the same time somewhat extended. The publication commenced very soon after, and from 1854 to 1863, thirty-six charts, of which some contained not less than 3,000 stars, were put into the hands of astronomers.

During the construction of these charts, Chacornac discovered many small planets—Amphitrite (March 3, 1854), Polymnia (October 28, 1854), Circe (April 6, 1855), Lydia (January 12, 1856), Lætitia (February 8, 1856), Olympia (September 12, 1860). At the same time he observed all the comets which were then visible and defined, with the telescope of Foucault, of 80 centimetres, many spiral nebulæ, previously studied by Herschel. The drawings of M. Chacornac are among the most careful we possess, and appear to show that nebulæ of this kind undergo in time slight variations of form.

This collection of remarkable works brought to the Astronomer of the Paris Observatory many academic and honorary rewards: thus, he obtained the Lalande Prize in 1852, 53, 54, 55, 56, 60, and 1863, became titular astronomer February 22, 1857, and Chevalier of the Legion of Honour, August 15, 1857.

His labours, however, and their attendant anxieties, told upon his health. After going to Spain, where he went to observe the total eclipse of the sun of July 18, 1860, the ecliptic charts were issued less frequently, and in June, 1863, he quitted the Observatory to retire to Ville Urbanne, in the suburbs of Lyon.

In his country retirement, M. Chacornac, whose spirit had preserved all its activity, constructed with his own hands a telescope of three metres focus, by means of which, until within the last few months, he assiduously observed the solar spots and their manifold transformations. In the description of their incessant changes he sought new proofs of the gaseous nature of the sun, an idea which he was one of the first to announce.

* From an article in *La Revue Scientifique*, by M. G. Rayet, Chief Astronomer of the Meteorological Service at the Paris Observatory.

SCIENCE LECTURES AT CAMBRIDGE

THE following Lectures in Natural Sciences will be given at Trinity, St. John's, and Sidney Sussex Colleges during Michaelmas Term, 1873:—

On General Physics and Mechanics. By Mr. Trotter, Trinity, in Lecture Room No. 11 (Monday, Wednesday, Friday, at 11, commencing Wednesday, Oct. 15).

On Elementary Organic Chemistry. By Mr. Main, St. John's (Tuesday, Thursday, Saturday, at 12, in St. John's College Laboratory, commencing Thursday, Oct. 16). Instruction in Practical Chemistry will also be given.

On Palæontology (the Protozoa and Cœlenterata). By Mr. Bonney, St. John's (Tuesday and Thursday at 9, commencing Thursday, Oct. 16).

On Geology for the Natural Sciences Tripos. Preliminary matter and Petrology. By Mr. Bonney, St. John's (Monday, Wednesday, and Friday, at 10, commencing Wednesday, Oct. 15.) A Course on Physical Geology will be given in the Lent Term, and on Stratigraphical Geology in the Easter Term.

Papers will be given to Questionists every Saturday at 11, but the first paper will be set on Wednesday, Oct. 15, at 11, when arrangements will be made for further instruction should it be required.

On Botany, for the Natural Sciences Tripos. By Mr. Hicks, Sidney (Tuesday, Thursday, Saturday, at 11, in Lecture Room No. 1, beginning on Thursday, Oct. 16). The Lectures during this term will be on the Morphology of Phanerogamia.

A Course of Practical Physiology and Histology. By the Trinity Prælector in Physiology (Dr. Michael Foster) at the New Museums. Lectures on Tuesday, Thursday, Saturday, at 12, commencing Saturday, Oct. 25.

This course is intended for those who have gone through a course of Elementary Biology similar to that given last Easter Term.

THE AMERICAN ASSOCIATION

THE Portland Meeting of the American Association for the Advancement of Science was in almost every respect an exceptional success. Its general attendance was very large, and there was an unusual number of the older members, whose presence insures consideration of the more important topics, and gives dignity and force to the discussions. An especial effort had been made to exclude all inferior communications. A regulation had been adopted, compelling the presentation of an abstract of each paper before it was read; and the examining committee in determining from abstracts what papers should be read, exercised in general a rigorous but wise discretion. It will not be the case after this, as after previous meetings, that a considerable proportion of the communications actually read will have to be ignored in the printed proceedings. But even under such restrictions, the number of papers actually read was unusually

large, and there were but few instances, as compared with previous years, of the pernicious practice of reading papers by title only—a practice which, if pushed to its logical conclusion, would result in the destruction of the meetings.

The discussions were kept well in hand, wandering but little from the subject, and being, though frequently brilliant, notably brief. There was in them almost an entire absence of any display of feeling, except an occasional expression of kindly regards between opponents whose differences did not extend beyond the debate; in fact, the cordiality of the meeting was one of its prominent features.

The newspaper press sent correspondents from distant cities—New York, Boston, and Chicago being well represented. The *New York Tribune* announced that its reports would be re-published in an extra, and determined to make that extra cover, with at least a fair extract, every communication read and accepted at the meeting, and the discussions elicited. The practical difficulties in the way of such an undertaking are considerable. All the sub-sections of the Association carry on their proceedings in separate rooms simultaneously. Many of the communications are technical, abstruse, and difficult to report, and have not been reduced to writing; it being the custom of some authors to delay preparation of MSS. for the official report till some months after the close of the meeting. Notwithstanding these obstacles and the expense involved in overcoming them, the extra was brought out with all the completeness proposed; thus anticipating the usual official publication by almost a year. It is a sheet of eight pages, and gives also an illustrated series of letters upon Deep Sea Dredging, as practised by the United States Commission of Fish and Fisheries, the whole containing as much reading-matter as would make a large duodecimo volume. The extra is sold for ten cents, this price including postage.

NOTES

SIR SAMUEL and Lady Baker arrived in London on Thursday evening last. The young African, a lad of about fifteen or sixteen years of age, in whom Lady Baker is said to take much interest, accompanied the party. Both Sir Samuel and Lady Baker looked well, and seemed in excellent spirits.

FOR the Biological Fellowship examination at Magdalen College, Oxford, there are five candidates, of which we are surprised to hear that three are graduates of the University of Cambridge. The election takes place on Saturday next.

MR. EDWARD BAGNALL POULTON, from Mr. Watson's School, Reading, has been elected to an open Physical Science Scholarship of 80*l*. per annum, in Jesus College, Oxford.

MISS POGSON, daughter of the Government Astronomer at Madras, has been appointed Assistant Astronomer.

THE American aëronaut, Mr. Samuel A. King, intends during September to make an extended balloon voyage from Buffalo, New York. For this purpose he is building a large balloon to replace the "Mammoth," which was destroyed by the recent great fire in Boston. It is Mr. King's purpose to make the longest overland voyage, if circumstances favour, ever yet accomplished. It is no part of his plan to go out over the ocean, nor to explore the sea, but he expects to be able to settle something about the upper currents when he comes down. His voyage is undertaken wholly in the interest of science, and, in view of the extraordinary degree of attention now being drawn to the subject of meteorology, the results will be regarded as of much more than ordinary importance. From a communication made by Mr. King in 1871 to the Washington Philosophical Society, it appeared that out of 170 aërial voyages made by him during the past twenty-five years, about twenty-five per cent. showed that the currents of the atmosphere were moving to the north-eastward; a second twenty-five per cent. gave westerly currents; and a third gave north-westerly currents. The remaining forty voyages were about equally distributed among northerly, southerly, and easterly currents. Mr. King's experience, therefore, agrees with that of most European aëronauts, who have repeatedly testified that there is no constant westerly current of air prevailing at any altitude above the earth's surface which they have been able to reach in their balloons.

CANADA is doing its part toward the exploration of the Great West. Besides the surveying parties out on the route of the Pacific Railroad, it has special parties in the field in connection with the Geological Survey and the Boundary Commission. Mr. Selwyn, F.G.S., Director of the Survey, and Mr. R. Bell, F.G.S., are at work on the great regions watered by the North Saskatchewan, and Mr. Richardson on the other side of the Rocky Mountains in British Columbia. Mr. G. M. Dawson, Associate of the School of Mines, Geologist of the Boundary Commission, has just completed a survey of the Lake of the Woods and its neighbourhood, and is now exploring the plains westward of Pembina. All these parties are provided with the means of making collections in the botany and zoology of the regions explored.

MR. J. A. HARVIE BROWN has sent us a reprint of an article by him which appeared in the *Scottish Naturalist* for July, advocating the establishment of a British Naturalist's Agency, on the model of the "American Naturalist's Agency," established at Salem, Mass. U.S. The American Agency has flourished and brought forth abundant and good fruit, and in an incredibly short space of time has become the acknowledged medium for the sale of the proceedings of all the learned societies in America, and through which advertisers on all natural history subjects make known their wants. The main purpose of the Agency is to facilitate the circulation of papers and pamphlets on Natural History, which, from the want of such an Agency, many who wish to possess them find it difficult to obtain, and which are often not even known beyond a narrow local circle. The Agency also undertake to publish new and republish old standard works in Natural History, and perform several other eminently useful offices which can only be sufficiently performed by some such central organisation. The very existence of such an Agency would create a demand for scientific knowledge. Such an Agency in this country would undoubtedly prove a great boon to naturalists, provided it were ably conducted, and fully acknowledged and supported by the leading scientific societies. Scientific circles in time, we believe, would be enlarged, and not be confined to the metropolis, or nearly so. There are plenty of good men out of London, Edinburgh, Glasgow, and the large towns who have no opportunities of reading, being removed from the principal scientific libraries. Not one individual, nor indeed any one society, could set such an undertaking afloat, but if all the leading societies would jointly discuss its merits and demerits, and at length bring it carefully and repeatedly before the notice of the British Association, there is every likelihood that it would become a complete success. To arrive at this first step it is necessary to ventilate the suggestion, and this cannot be better done than by bringing it before the notice of the local societies, and asking each to assist in bringing it finally before a higher court. Parties interested and desirous of seeing such a scheme successful may communicate with Dr. F. Buchanan White, editor of *Scottish Naturalist*, Perth, or with John Harvie Brown, Dunipace House, Falkirk.

ON Monday last a meeting was held at the Mansion House with the view of promoting technical education in the City. The

meeting was immediately held in connection with the distribution of prizes by the Turners' Company, for the best specimens of workmanship in the turning of articles in ivory and stone. It is creditable to this Company that it has by this means been endeavouring to promote technical education for some years past, and if all the other City Companies took the trouble to follow the Turners' example, and encourage the introduction into the various trades and handicrafts with which they are connected of a scientific method of workmanship founded upon scientific knowledge of material and on sound scientific theory, we believe they would be doing eminent service that would be fruitful of the best results to the trade and commerce and manufactures of the kingdom.

MR. T. W. BURR writes us that he has, since 1853, been in the habit of using a sidereal dial similar to that described by Captain Mayne, in NATURE, vol. viii. p. 366.

THE death of Prof. John Lewis Russell is announced as having taken place at Salem, U.S., on the 7th of June, in the sixty-fifth year of his age. Prof. Russell was well known as an ardent student of botany, and especially in the department of New England cryptogams, in which he was a recognised authority. He took much interest in the scientific societies of Salem, having been connected more or less with their foundation and administration during the active years of his life.

PROF. AGASSIZ has recently lost one of his most valuable assistants in the death of Dr. G. A. Maack, on the 6th of August last, in the thirty-third year of his age. He was connected with the Cambridge Museum for several years, during which time he was detailed by his chief to act as geologist of the Darien Isthmus exploring party, under Commander Selfridge, and also prosecuted similar researches in Brazil and elsewhere in South America. He was specially charged with the osteological collection of the Cambridge Museum, which he managed with great ability.

THE death is announced of Mr. George Ormerod, of Sedbury Park, Gloucestershire, F.R.S., F.S.A., D.C.L., &c., a well-known antiquary. He was eighty-seven years of age.

THE *Journal of Botany* records the death of Dr. J. Lindsay Stewart, late Conservator of forests in the Punjaub, who had rendered great service to the cause of forest administration in India, by the commencement of the large and now flourishing plantations in the plains of the Punjaub, and who was also a copious writer on Indian botany.

"CONTRIBUTIONS to our knowledge of the Meteorology of the Antarctic Regions," published by the Meteorological Committee, will be of value both to meteorologists and to future Antarctic navigators. The work has been executed by Mr. R. Strachan, and the materials which form the paper have been extracted from the Meteorological Registers kept in the Antarctic Regions, on board H.M.S. *Erebus* and *Terror*, during the months December 1840—March 1841, December 1841—March 1842, December 1842—March 1843, and on board H.M. sloop *Pagoda* during January–March 1845.

As a result of the inquiry into the recent typhoid epidemic, we are glad to see that the Dairy Reform Company have secured the co-operation of Prof. Corfield, M.D., Prof. Voelcker, Ph.D., and Prof. Wanklyn, to carry out the precautions which have been adopted. A medical and veterinary examination of the employes and stock on each farm is made every week, and reports are forwarded to the Company's chief office in Orchard Street, where they are open to the inspection of customers from 10 A.M. to 4 P.M., on week days. Orders of admission to all their establishments have been given to the medical officers of health for the following districts:—St. James's, Marylebone, Kensington, St. George's, Paddington, Chelsea, and St. Pancras.

WITH reference to our note in last week's number concerning the *Leeds Daily News*, we are glad to be able to say that the *Leeds Mercury* and the *Yorkshire Post and Leeds Intelligencer* also report the transactions of the Leeds Naturalists' Field Club.

MESSRS. CHURCHILL have in the press and will publish during the ensuing season the following works of interest to scientific men:—"On Food, Physiologically, Dietetically, and Therapeutically considered," by F. W. Pavy, M.D., F.R.S.; a third and enlarged edition of Dr. Lionel Beale's "Protoplasm, Dissentient Demonstrative, and Speculative," with 16 plates; a second edition of "The Thanatophidia of India," by J. Fayrer, M.D., C.S.I.; a new illustrated work on "Medicinal Plants," by Robert Bentley, F.L.S., and Henry Trimen, M.B., F.L.S. This work will include full botanical descriptions and an account of the properties and uses of the principal plants employed in medicine, especial attention being paid to those which are officinal in the British and United States Pharmacopœias. The plants which supply food and substances required by the sick and convalescent will be also included. Each species will be illustrated by a coloured plate drawn from nature. This work will be published in monthly parts, of which we may expect the first very shortly. A translation by Arthur E. J. Barker, of Frey's "Manual of the Histology and Histo-Chemistry of Man," a treatise on the elements of structure and composition of the human body; the book will be largely illustrated with engravings on wood, and specially revised by the author. "The Microscope and its Revelations," by Dr. W. B. Carpenter, F.R.S.; a new edition with upwards of 500 engravings." "Experimental Investigations of the Action of Medicines;" being a handbook of Practical Pharmacology, with engravings, by T. Lauder Brunton, M.D., one of the lecturers at St. Bartholomew's Hospital; "The Student's Guide to Zoology," with engravings on wood, by Andrew Wilson, Lecturer on Zoology at Edinburgh and author of "Elements of Zoology;" "On Long, Short, and Weak Sight, and their Treatment by the Scientific use of Spectacles," by J. Soelberg Wells, F.R.C.S., fourth edition, with engravings.

MESSRS. BLACKWOOD will shortly publish, "Economic Geology, or Geology in its relation to the Arts and Manufactures," by David Page, LL.D.; and an "Advanced Text-Book of Botany," for the use of Students, by Dr. Robert Brown, F.R.G.S., with numerous Illustrations.

MESSRS. STRAHAN & Co. announce, as nearly ready, "The Great Ice Age and its Relation to the Antiquity of Man," by James Geikie, F.R.S.E., of H.M. Geological Survey. This work will be copiously illustrated.

THE third session of the Newcastle College of Science commenced on Tuesday, presided over by the Dean of Durham. Prof. Herschel delivered an address. The necessity for shortly providing more accommodation was considered, and it was understood that an effort was about to be made to raise funds for a new college. The very rev. chairman also mentioned that a College of Agriculture was about to be founded in Central Northumberland in connection with the University of Durham.

THE annual distribution of prizes to the successful competitors in the Guildford Science and Art classes, awarded by the Government Department of Science and Art, took place on the evening of October 1, at the Town Hall. In addition to the Guildford prizes those won by the students of St. John's, Woking, were also distributed, as well as the Night Art Class of the Guildfold Working Men's Institute. The number of students has continued steadily to increase upon former years, 62 having

attended the classes during the last winter session. Of these, 35 came up for examination in May, and 23 passed. Several of these obtained very advanced success in more than one subject, so that the total number of successful candidates in the seven subjects taught amounts this year to 49, including four outside candidates, leaving an increase of 13 from last year. Mr. Ethelbert Dowlen, one of the pupils, has been awarded the "Queen's Silver Medal" in botany, and besides numerous other prizes and certificates, he also obtained the "Queen's Gold Medal" for geology at St. John's College, Woking. Altogether these classes seem to have been highly successful, and we hope they will continue to be increasingly so. The classes will be re-opened for instruction on Tuesday, 27th inst., and will be continued every Monday and Wednesday evening for Physical Geography, and on Tuesdays and Fridays, from 6 to 9 P.M., in the other subjects. A class will be held on Saturdays for ladies, in Botany, at a convenient time, commencing from the 11th inst. at 11 A.M. Proposed Subjects :—1, Mathematics (1st, 2nd, and 3rd stage), or theoretic mechanics ; 2, sound, light, and heat ; 3, magnetism and electricity ; 4, chemistry, inorganic ; 5, animal physiology ; 6, elementary botany ; 7, biology ; 8, physical geography. The fees are very moderate.

THE volume of Artizans' Reports upon the Vienna Exhibition, published by the Society for the Promotion of Scientific Industry, Manchester, will be published about the 20th of this month. There are thirty-six reports, which are said to be of a very high-class character.

WE are glad to see, from the Report of the Chester Society of Natural Science, that that Society, which has concluded its second year, continues to increase in prosperity so far as numbers are concerned—the number of members being now 454. Among these are not a few working members ; and the secretary gives excellent advice in counselling each member to devote himself to a special subject, as thus only can the interest of the Society and the advance of science be best promoted. During the past year two societies of natural science have been founded in the neighbourhood of Chester—one at Wrexham, the other at Whitechurch. The Chester Society does its work by means of field excursions, general lectures, and sectional meetings.

THE forthcoming number of Petermann's *Mittheilungen* will contain a detailed account of Captain Hall's *Polaris* Arctic expedition, with its scientific results. It will be accompanied by a carefully constructed map showing the course of the *Polaris* from the 80th degree northwards, her course southward from Aug. 15 to Oct. 15, 1872, the course along which the floe containing the nineteen persons drifted after they were separated from the ship on the night of Oct. 15, 1872, until they were picked up off the coast of Labrador six months afterwards, the distance drifted each day, along with the state of the weather, and the places where seals, &c. were obtained, being indicated ; and lastly, the course taken by the men who were picked up in Melville Bay last June.

SHORTLY before his death the late Colonel J. W. Foster completed the manuscript of a work upon the prehistoric races of the United States, which has just made its appearance from the press of S. C. Griggs and Co., of Chicago. This contains an excellent summary of the present state of our knowledge of the aborigines of North America, as illustrated by the remains found in mounds, shell heaps, and ancient mines, as well as by their crania.

THE City of London College, Leadenhall Street, to judge from the programme we have received, offers excellent opportunities to young men engaged during the day for obtaining a good education, literary and scientific, and for intellectual improvement in various ways.

THE *Times of India* says that a scientific geographical survey of native Sikkim is in contemplation by the authorities.

THE *Geological Magazine* announces the death of Prof. Dr. Kemp of Darmstadt, a distinguished zoologist and palæontologist, whose name is well known in connection with the discovery of the *Dinotherium*.

HERR SCHLOENBACH, proprietor of certain salt works at Lieberhall, in Hanover, has instituted a foundation of 12,000 florins, the interest of which is to be devoted to assist geologists who may undertake journeys of exploration beyond the Austro-Hungarian empire. This is intended as a memorial tribute to his son, a young German geologist of much promise, recently deceased.

THE additions to the Zoological Society's Gardens during the last week include an Arctic Fox (*Canis lagopus*) and an Iceland Gull (*Larus leucopterus*), European, presented by Mr. B. L. Smith ; a Black-handed Spider-monkey (*Ateles melanochir*) from South America, presented by Mr. B. Went ; an African Civet Cat (*Viverra civetta*), presented by Lady Cust ; a Macaque Monkey (*Macacus cynomolgus*) from Africa, presented by Capt. Denison ; a Raccoon (*Procyon lotor*) from North America, and a Vulpine Phalanger (*Phalangista vulpina*) from Australia, presented by Miss Breach.

THE BRITISH ASSOCIATION

SECTIONAL PROCEEDINGS

SECTION A.—MATHEMATICS

On the Introduction of the Decimal Point into Arithmetic, by J. W. L. Glaisher, B.A.

The following is an extract from Peacock's excellent History of Arithmetic, in the "Encyclopædia Metropolitana," which forms the standard (not to say the only) work on the subject. Speaking of Stevinus's "Arithmétique," Peacock writes : "We find no traces, however, of decimal arithmetic in this work, and the first notice of *decimal*, properly so called, is to be found in a short tract, which is put at the end of his 'Arithmétique,' in the collection of his works by Albert Girard, entitled 'La Disme.' It was first published in Flemish, about the year 1590, and afterwards translated into barbarous French by Simon of Bruges. . . . Whatever advantages, however, this admirable invention, combined as it still was with the addition of the exponents, possessed above the ordinary methods of calculation in the case of abstract or concrete fractions, it does not appear that they were readily perceived or adopted by his contemporaries. . . . The last and final improvement in this *Decimal Arithmetic*, of assimilating the notation of integers and *decimal* fractions, by placing a *point* or *comma* between them, and omitting the exponents altogether, is unquestionably due to the illustrious Napier, and is not one of the least of the many precious benefits which he conferred upon the science of calculation. No notice whatever is taken of them in the 'Mirifici Logarithmorum Canonis Descriptio,' nor in its accompanying tables, which was published in 1614. In a short abstract, however, of the theory of these logarithms, with a short table of the logarithms of natural numbers, which was published by Wright, 1616, we find a few examples of decimals expressed with reference to the decimal point ; but they are first distinctly noticed in the 'Rabdologia,' which was published in 1617. In an 'Admonitio pro decimali Arithmetica,' he mentions in terms of the highest praise the invention of Stevinus, and explains his notation ; and without noticing his own simplification of it, he exhibits it in the following example, in which it is required to divide 861094 by 432. . . . The quotient is 1993,273, or 1993,2′7″3‴, the form under which he afterwards writes it, in partial conformity with the practice of Stevinus. The same form is adopted in an example of abbreviated multiplication, which subsequently occurs. . . . The preceding statement will sufficiently explain the reason why no notice is taken of *decimals* in the elaborate explanations which are given by Napier, Briggs, and Kepler, of the theory and construction of logarithms ; and indeed we find no mention of them in any English author between 1619 and 1631. In that year the 'Logarithmicall Arith-

metike,' was published by Gellibrand, and other friends of Briggs, who died the year before, with a much more detailed and popular explanation of the doctrine of logarithms than was to be found in the 'Arithmetica Logarithmica.' It is there said . . . From this period we may consider the decimal arithmetic as fully established, inasmuch as the explanation of it began to form an essential part of all books of practical Arithmetic. The simple method of marking the separation of the decimals and integers by a comma, of which Napier has given a solitary example, was not however generally adopted." . . .

De Morgan ("Arithmetical Books," 1847, p. xxiii.) writes: "Dr. Peacock mentions Napier as being the person to whom the introduction [of the decimal point] is unquestionably ue; a position which I must dispute upon additional evidence. The inventor of the single decimal distinction, be it point orli ne, as in 123·456, or 123 | 456, is the person who first made his distinction a permanent language; not using it *merely as a r.st in the process*, to be useful in pointing out afterwards how another process is to come on, or language is to be applied, but making it his final and permanent indication as well of the way of pointing out where thei ntegers end and the fractions begin, as of the manner in which that distinction modifies operations. Now first I submit that Napier did not do this; secondly, that if he did do this, Richard Witt did it before him."

De Morgan then states that he has not seen Wright's translation of 1616, but he proceeds to examine Napier's claim as resting on the two examples in the "Rabdologia," in the first of which a comma is used, but only in one place. After this examination he proceeds, "I cannot trace the decimal point in this: but if required to do so, I can see it more distinctly in Witt, who published four years before Napier. But I can hardly admit him to have arrived at the notation of the decimal point. . . ."*

I agree with De Morgan in all that he has stated in the above extracts, and do not think that the single instance of the comma used in the course of work, and replaced immediately afterwards by exponential marks, is a sufficient ground for assigning to Napier the invention of the decimal point, or even affords a presumption that he made use of it at all in the expression of results.

Still one of the objects of this paper is to claim (provisionally of course, till evidence of any earlier use is produced, if such there be) the invention of the decimal point for Napier, but not on account of anything contained in the "Rabdologia." The mathematical works published by Napier in his life-time (he died in 1617) were his "Mirifici Logarithmorum Canonis Descriptio," 1614, containing the first announcement of the invention of logarithms, and the "Rabdologia," 1617, giving an account of his almost equally remarkable (as it was thought at the time) invention of numbering rods or "bones." In 1619, two years after his death, the "Mirifici Logarithmorum Canonis Constructio," containing the method of construction of the canon of logarithms was published, edited by his son, and in this work the decimal point is systematically used in a manner identical with that in which we employ it at the present day. I can find no traces of the decimal point in Wright's translation of the "Descriptio," 1616; and, as De Morgan says, the use of the decimal separator is not apparent in Witt. The earliest work, therefore, in which a decimal separator was employed seems to be Napier's posthumous work, the "Constructio" (1619), where the following definition of the point occurs on p. 6. "In numeris periodo sic in se distinctis, quicquid post periodum notatur fractio est, cujus denominator est unitas cum tot cyphris post se, quot sunt figuræ post periodum. Ut 10000000·04 valet idem, quod $10000000\frac{4}{100}$. Item 25·803, idem quod $25\frac{803}{1000}$. Item 9999998·0005021, idem valet quod $9999998\frac{5021}{10000000}$, et sic de cæteris." On p. 8 we have 10·502 multiplied by 3·216, and the result found to be 33·774432; and on pp. 23 and 24 occur decimals not attached to integers, viz. ·4999712 and ·0004950. These show that Napier was in possession of all the conventions and attributes that enable the decimal point to complete so symmetrically our system of notation, viz. (1), he saw that a point or separatrix was quite enough to separate integers from decimals, and that no signs to indicate primes, seconds, &c., were required; (2), he used ciphers after the decimal point and preceding the first significant figure, and (3), he had no objection to a decimal standing by itself without any integer. Napier thus had complete command over decimal fractions and understood perfectly the nature of the decimal point, and I believe (except perhaps Briggs) he is the first person of whom this can be said. When I first read the "Constructio," I felt some doubt as to whether Napier really appreciated the value of the decimal point in all its bearings, as he seemed to have regarded it to some extent as a mark to separate figures that were to be rejected from those that were to be retained; but a careful examination has led me to believe that his views on the subject were pretty nearly identical with those of a modern arithmetician. There are perhaps 200 decimal points in the book, affording abundant evidence on the subject.

The claim of Napier to the invention of the decimal point is not here noticed for the first time, as both Delambre ("Hist. de l'Astron. mod. t. i. p. 497) and Hutton allude to the decimal fractions in the "Constructio" (though the latter claims priority for Pitiscus), and Mr. Mark Napier ("Memoirs of John Napier," p. 454) devotes a good deal of space to it.

Briggs also used decimals, but in a form not quite so convenient as Napier; thus, he writes 63·0957379 as $63\underline{0957379}$, viz., he prints a bar under the decimals: this notation first appears without any explanation, in his "Lucubrationes" appended to the "Constructio."* Briggs used this notation all his life (he died in 1631), and he explains it in the "Arithmetica Logarithmica" of 1624. Oughtred's symbol first used (as far as I know), in his "Arithmeticæ in numeris"...Clavis, 1631, differed only from Briggs's in the insertion of a vertical bar to separate the decimals from the integers more completely, thus: 63 | 0957379. Oughtred's and Briggs's notation are essentially the same, the improvement of the former being no doubt due to the uncertainty that sometimes might be felt as to which was the first figure above Briggs's line.

From an inspection of MSS. of Briggs and Oughtred (the Birch MSS. contain a letter of Briggs's to Pell, and the Royal Society has a Peter Ramus with many of his MS. notes, while the Cambridge University copy of the "Constructio" is annotated in MS. by Oughtred), it is apparent that in writing, Briggs and Oughtred both made the separating rectangle in exactly the same way, viz., they wrote it 63 | 0957379, the upright mark usually being just high enough to fix distinctly what two figures it was intended to separate, and rarely took the trouble to continue the horizontal bar to the end of the decimals, if there were many. Thus Oughtred was a follower of Briggs, and only made an improvement in the *printed* notation. It is clear that in writing Briggs's rectangle was pretty nearly as convenient as Napier's point, and there is every probability that Briggs appreciated all the properties of the "separatrix" as clearly as Napier; but in his 8 pp. of "Lucubrationes" he has left much less to judge by than has Napier. In 1624, as we can see from his "Arithmetica Logarithmetica," he had full command over decimal arithmetic in its present form (except that he used the rectangular "separatrix" instead of the point). Gunter was a follower of Napier, and employed the point (but see De Morgan). In his "Description and Use of the Sector" (1623), he uses the point throughout pretty much as we do at present (*e.g.* p. 41 of the "First Booke of the Crosse-staffe": "As 4·50 unto 1·00 : so 1·000 unto 0·222"), except that he calls the decimals *parts* in the text. In Roe's "Tabulæ Logarithmicæ, or Two Tables of Logarithme" (1633), the explanatory portion of which was written by Wingate, decimal points are used everywhere; thus we have (p. 29): "As 1 is to ·079578 : so is the square of the circumference to the superficial content," and he takes the case of circumference 88·75, and obtains by multiplication (performed by logarithms) 626·8 for the result. Wingate refers for explanation on the decimal point to his arithmetic, but I have not seen any edition of this work that was published previously to Roe's tables (Watt gives one, 1630). In his "Construction and Use of the Line of Propotion" (1628), Wingate also uses decimals and decimal points.

On the whole, therefore, it appears that both Napier and Briggs saw that a mere separator to distinguish integers from decimals was quite sufficient, without any exponential marks being attached to the latter; but that Napier used a simple point for the purpose, while Briggs employed a bent or curved line, for which in print he substituted merely a horizontal bar

* In an essay "On some points in the History of Arithmetic" (Companion to the Almanac for 1851), De Morgan has further discussed the invention of the decimal point, but in the same spirit as regards Napier. He seems never to have seen Napier's "Constructio" of 1619, and the work is very rare. The only copy I have been able to see is that in the Cambridge University Library.

* A curious blunder is made in Bartholomew Vincent's reprint of the "Constructio," Lyons, 1620 (of which there is a copy in the Royal Society's library). The printer, unaware that the position of Briggs's subscript bars had any meaning, has disposed them symmetrically under all the figures.

subscript to the decimals; that Gunter and Wingate followed Napier, while Oughtred adopted Briggs's method and made an improvement in the mode of *printing* it. Napier has left so many instances of the decimal point as to render it pretty certain that he thoroughly appreciated its use; and there is every reason to believe that Briggs had, in 1619, an equal command over his separator, although there are not enough printed instances of that date to prove it so conclusively as in Napier's case (there is no instance in the "Lucubrationes" in which a quantity begins with a decimal point, and there could not well be one). Napier did not use the decimal point in the "Descriptio" (1614), nor in his book of arithmetic first printed under the editorship of Mr. Mark Napier in 1839, and there is only the single doubtful case in the "Rabdologia," 1617, so that there is reason to believe that he did not regard it as generally applicable in ordinary arithmetic. The only previous publication of Briggs's that I have seen was his "Chilias," 1617, which contains no letterpress at all. The fact that Napier and Briggs use different separating notations is an argument against either having been indebted to the other, as whoever adopted the other's views would probably have accepted his separator too. It is doubtful whether, if Napier had written an ordinary arithmetic at the close of his life he would have used his decimal point. Wingate employed the decimal point with much more boldness, and regarded it much more in the light of a permanent symbol of arithmetic than did (or could) Napier. The Napierian point and the Briggian separator differ but little in writing, and as far as MS. work is concerned it is quite easy to see why many should have considered the latter preferable, for it was clear and interfered with no existing mark. A point is the simplest separator possible, but it had already another use in language. In all the editions of Oughtred's "Clavis" (which work held its ground till the beginning of the last century) the rectangular separator was used, and it is not unlikely that it was ultimately given up for the same reason as that which I believe will lead to the abandonment of the similar sign now used in certain English books to denote factorials, viz., because it was troublesome to *print*. But be this as it may, it is not a little remarkable that the first separator used (or more strictly, one of the first two) should have been that which was finally adopted after a long period of disuse. All through the seventeenth century exponential works seem to have been common, on which see the accounts in Sir Jonas Moore's "Moor's Arithmetick," London, 1660, p. 10; and Samuel Jeake's "Compleat Body of Arithmetick," London, 1701 (written in 1674), p. 208, which are unfortunately too long to quote in this abstract. In his account Peacock is inaccurate in saying that the "Logarithmicall Arithmetike" was published by Gellibrand and others, the mistake having arisen, no doubt, from a confusion with the "Trigonometria Britannica," 1633; and in any case the reference is not a good one, as the "Arithmetike" of 1631 shows (for reasons which must be passed over here) a less knowledge of decimal arithmetic than do any of the chief logarithmic works of this period. Also Briggs died in 1631, not 1630.

There is no doubt, whatever, that decimal fractions were first introduced by Stevinus in his tract, "La Disme." De Morgan ("Arithmetical Books," p. 27) is quite right in his inference that it appeared in French in 1585, attached to the "Pratique d'Arithmétique." A copy of this work (1585) with "La Disme" appended, is now in the British Museum. On the title-page of the "Disme" are the words "Premierement descripte en Flameng, et maintenant conuertie en François, par Simon Stevin de Bruges." These words appearing also in Albert Girard's collected edition of Stevinus's works (1634) no doubt gave rise to De Morgan's inference that "the method of decimal fractions was announced before 1585 in Dutch." The Cambridge University Library possesses a 1585 copy, entitled "De Thiende... Beschreven door Simon Stevin van Brugghe....Tot Leyden. By Christoffel Plantijn, M.D. LXXXV." (privilege, dated December 20, 1584), and there seems every reason to believe, in the absenc of any evidence to the contrary, that this was the first edition of this celebrated tract. Peacock's statement that "it was first published in Flemish about the year 1590, and afterwards translated into barbarous French by Simon of Bruges" is also, I suspect, founded on no other evidence than the sentence on the title-page of the "Disme," which appears also in Girard. De Morgan rightly remarks that Simon of Bruges is Stevinus himself, but he cannot tell whence Peacock derived the date 1590. It is probable that it was merely a rough estimate obtained by considering the dates of the other works of Stevinus.

Stevinus's method involved the use of his cumbrous exponents. Thus he wrote 27·847 as 27(0)8(1)4(2)7(3)* and read it 27 commencements, 8 primes, 4 seconds, 7 thirds; and the question chiefly noticed in this abstract is the consideration of who first saw that by a simple notation the exponents might be omitted, and introduced this abbreviation into arithmetic.

Napier's "Rabdologia" was translated into several languages soon after its appearance, and I have taken some pains to examine the different ways in which the translators treated the example which Peacock regarded as the first use of the decimal point, as we can thereby infer something with regard to the state of decimal arithmetic in the different countries. Napier (1617) wrote 1993,273 in the work, and 1993,2′7″3‴ in the text. In Locatello's translation (Verona, 1623) this is just reversed, viz. there is 1993.2′7″3‴ in the work, and 1993,273 in the text. The Lyons edition (1626) has 1993,273 in the work, and 1993,2(1)7(2)3(3)† in the text, while De Decker's edition (Gouda, 1626) has 1993,273 in the work, and in the text 1993(0)2(1)7(2)3(3), the last being exactly as Stevinus would have written it. Ursinus's "Rhabdologia," Berlin, 1623, is not an exact translation, and the example in question does not occur there.

SANITARY PROGRESS ‡

SANITARY science is a thing of yesterday, comparatively speaking; but sanitary art, the art of preserving the health, whether of individuals or of communities, has been studied and practised for ages. Sanitary science is the latest and highest development of medicine. I say it is the highest branch of medical science because of the extreme importance of its objects, and I may also add of its results. It is the study of the causes of diseases, and it points out the means of preventing them; and I am sure you are all agreed that "prevention is better than cure;" as Rollet of Lyons well said, "Medicine cures individuals, hygiene saves the masses." But while we contrast hygiene (another name for sanitary science) with curative medicine, we must not forget that it is altogether a medical science, and that its great lights have been all medical men (mind, I am not speaking of the art now, but of the science), and this is necessarily so, and always must be so. I have said that sanitary science is the study of the causes of diseases, of the modes in which they originate, and in which they spread from one person or place to another. It is therefore only those who are acquainted with disease, that are competent to deal with it all, and these are those who have made medical science generally their special subject. You sometimes hear it said that medical men don't know much about diseases. Just think what this means; disease has been studied by earnest men in all its various forms for thousands of years; experiences have been recorded, comparisons made; the effects of remedies noted from generation to generation, and yet we are asked to believe that medical men don't know anything about diseases; the thing is absurd on the face of it.

Sanitary science is, then, a medical science, and the most intimate acquaintance with diseases is necessary for its prosecution —I mean for its advancement as a science. Sanitary investigations can only be scientifically conducted by medical men, just as pianos can only be played by musicians. This science is also the latest development of medical science. We must understand simple things before we can study complex ones. It is little use for a boy to study higher algebra until he has mastered the rule of three; and so pathology, or the study of diseased actions, becomes more and more advanced as physiology—the study of normal healthy actions—is more scientifically pursued; while the study of sanitary matters in a scientific way has only become possible of later years from the great advances made in the study of pathology, physiology, and chemistry; but being possible, it has made such rapid strides, and evolved such startling facts with regard to the causes of diseases, that it has become the popular subject of the day. Everyone thinks that he is competent to speak about it, and everyone who wants to make an effective discourse must needs take upon himself to expound

* Stevinus enclosed the exponent-numbers in complete circles, which have been replaced above, for convenience of printing, by parentheses.

† These parentheses are printed instead of the circles which appear in these works as in Stevinus.

‡ Abstract of the Inaugural Lecture delivered at the Town Hall, Birmingham, Thursday evening, Oct. 9, 1873, by Prof. Corfield, M.D. Oxon.

some, to him, new view ot sanitary matters; this is very mischievous. A man may do more harm by giving the weight of his authority to erroneous views respecting the method to be employed for the prevention of diseases than he has done good during the whole of his life in any other way. None but those who have made a special study of this subject have a right to speak on it, or at any rate have a right to influence the public mind with regard to it. The amount of good which may be done by the exposition of correct views on sanitary matters is incalculable; the amount of evil done by the enunciation of erroneous views, backed by apparent authority, fearful.

But if sanitary science is a thing of yesterday, such is not the case with the observation of sanitary facts, nor with the practice of sanitary art; and, while it is true that sanitary science is essentially and entirely a medical study, and is necessarily so, it is equally true that the practice of the art of preserving the health is not only possible to all, but is a duty which devolves upon all. In all ages we have had writers on this subject. From all countries we may learn useful lessons about it. From the times of Hippocrates, Galen, and Celsus, we have had records of the results of observations on the methods of preserving the health; from the time of Moses we have had lawgivers imposing salutary conditions of existence upon unwilling, because ignorant populations. We look upon the immense engineering works undertaken and carried out by the Romans to supply their towns with pure water with astonishment, when we turn round and see our own towns supplied from polluted rivers, or, worse still, from shallow wells dug in the soil upon which they themselves stand, wells supplied in most cases chiefly by the foul water which has percolated from the surface of the ground. We have found out in later times that one of the main conditions of the health of communities depends on the purity of the drinking water, and we see that the Roman engineers, by having to go to a considerable distance for water in order to get it to a sufficient height in their cities, accidentally, as it were, fulfilled one of the most important of sanitary requirements.

"Knowledge is power," and as we come to know more of the conditions which favour the spread of diseases, as we do daily, it is our own fault if we neglect to use the power which that knowledge gives us. There are two conditions of insalubrity which are pre-eminent. I hardly know which to place first. The one is overcrowding, and the other the accumulation of refuse matters in and about dwellings. These conditions were those which especially favoured the spread of the fearful plagues of the middle ages; as a result of over-crowding we have a deteriorated condition of the air, from the diminution of the amount of its most essential constituent, oxygen; and, worse still, we have it rendered foul by the exhalation of decomposing organic matters from the bodies of the persons breathing it. Such a state of air is especially favourable to the multiplication of the poisons of diseases; such a state of the air is also brought about by the non-removal of refuse matters from the vicinity of habitations. Dr. Laycock tells us that the plague in York in each of its visitations, and also the cholera, broke out in the same abominably filthy place; and in cholera epidemics it has been repeatedly noticed that those parts of towns which are most filthy and most over-crowded, always suffer worst.

But the danger is not only from special epidemic diseases. Such insanitary conditions induce a lowered vitality of the inhabitants, who become prone to attacks of diseases of all sorts; and then we have sickness, inability to work, and consequent inability to earn bread and to pay rents, and so the evil recoils from the tenants upon the landlords. One witness says, "Rent is the best got from healthy houses." Another, "Sickness at all times forms an excuse for the poorer part not paying their rent, and a reasonable excuse."

I consider that one of the most important conclusions that the study of sanitary science has forced upon us lately is the conclusion that the immediate removal of refuse matters is one of the first necessities of the healthy existence of a community. There are those who would have you believe that refuse matters may be rendered innocuous in one way or another, so that they may be kept with safety in and near to houses. Don't listen to them; the principle is wrong—radically wrong. Depend upon it that the true method is to get rid of such matters at once, and in the simplest possible way, and that is the cheapest plan in the end. Show me a town where refuse matters are kept—no matter how they are treated—and I will show you a town where the standard of vitality is low; I will show you a town with a high death-rate, especially among children.

To take the other side of the question, look at London. There you have a population of $3\frac{1}{4}$ millions, with the lowest death-rate of any very large collected population in the world, with one of the lowest death-rates among the large towns of even our own country. Why is this? I say unhesitatingly, and without fear of contradiction, that with all allowances made for the excellent position of London, it is mainly due to the fact that the principle there, however incompletely it may be carried out, is the immediate removal of all refuse matters; in London, the water-carriage system, by which the foul water containing a very large proportion of the refuse matters of the population, is removed by gravitation in sewers, is carried out far more perfectly than in any other large town, and this system is daily being rendered more perfect there; it is the right system based upon a true principle, and its results are most salutary. When you have got rid of refuse matters, then see what you can do with them; and here arises a very curious consideration. Sewers, in most instances, were not originally built as sewers, but as drains; a sewer is a conduit for the removal of fouled water; a drain is a channel for the removal of mere superfluous water, the object being to dry the soil. The pattern of all our old sewers, the Cloaca Maxima at Rome, was originally a drain; it was constructed by Tarquinius Priscus, the fifth King of Rome, 600 years B.C., to drain the marshy ground between the Palatine and Capitoline hills, and it was so well constructed that it drains that ground at this moment. Pliny wondered that it had endured 700 years unaffected by earthquakes, by inundations of the Tiber, by masses which had rolled into its channel, and by the weight of the ruins which had fallen over it. What would he say could he see it now, as any of you may who choose to go to Rome, still discharging, after more than 2,400 years, its dirty water into the Tiber? But the convenience of the great drain for the disposal of refuse matters soon became apparent, and so it was turned into a sewer, and has been one ever since.

Well, what are we to do with the refuse sewer water, when we have got it out of our towns? This is one of the greatest questions of the day. Drains, of course, were naturally made to discharge into rivers, their proper place, so long as they were only drains; but when they come to be used as sewers, this will not do; in the first place the rivers are fouled, and in the next the manure is lost. I shall be able to show you in the course of the lecture that the only way known by which sewer water can be either purified or utilised, is by turning it, with suitable precautions, on to land, that this may be done, not only without injury to the health of the neighbourhood, but with great benefit in many ways.

We have spoken of drains to dry the soil; what is the necessity of this? Every farmer knows that crops will not flourish on undrained land; neither can human beings; a damp house is a synonym for an unhealthy house, you all know that; but it is only within the last few years, as the result of a most important sanitary research, made by Dr. Buchanan, that we have come to know as a scientific fact, beyond all dispute, that the drying of the soil of a town reduces the number of deaths from consumption in a most extraordinary manner; in some towns the number of deaths under this head has been reduced by one-third or even by one-half, in this way.

To mention some other special diseases which have been successfully combatted of late years, look at scurvy, that terrible malady which formerly decimated our navies! We know now that that disease may be prevented by the use of limejuice as part of the daily food, and we are no longer afraid of it. (Some illustrations of the ravages of this disease were given.)

Look at small-pox, beyond all exception the most fearful epidemic disease with which the world was ever afflicted! We know how to prevent it, and we have recently had a very severe lesson from not applying that knowledge. It is to the immortal credit of England that Jenner, the discoverer of vaccination, was an Englishman; there are certain people, and they have actually formed a society, who are trying to get compulsory vaccination done away with in this country. Let me tell you that if there is one fact established in preventive medicine it is that vaccination affords a protection from small-pox; let me tell you that this statement is founded upon an induction such as has been brought to bear upon no other subject in medical science; and, let me add, that those persons who bring isolated facts as arguments against a statement so supported, show that they have no idea of the nature of an inductive argument at all. An unvaccinated person is a danger to the community, and ought not to be allowed to go at large, and so far from persons being merely fined for

not allowing their children to be vaccinated, and then permitted to keep them unvaccinated, the children ought to be vaccinated by the public vaccinator, even in spite of their parents, who should not be allowed to risk their children's lives through their own obstinacy and ignorance; and not only their children's lives, but those of the persons around them. The recent epidemic of small-pox showed us several important things—it showed us what we knew before, that small-pox is far more fatal to unvaccinated than to vaccinated persons; it showed us that while small-pox is especially fatal to unvaccinated children, it is less fatal to vaccinated children than to other persons; thus demonstrating the necessity of re-vaccination, and it showed us that re-vaccination once performed is actually a better protection against small-pox than a previous attack of small-pox is. You know that it is not common for a person to have small-pox twice. Well, it is much less common for a person to have small-pox after he has been successfully re-vaccinated, and if he has it is almost certain to be a very mild attack. Out of nearly 15,000 cases of small-pox admitted into various London hospitals during the late epidemic, only four presented proof of having been re-vaccinated.

Let us pass on to typhoid fever. Here is a disease of the very existence of which, as distinct from certain other diseases, we have only known in recent times, but yet a disease about which, thanks to the researches of men now among us, one of whom it especially becomes me, as his pupil to mention, Sir William Jenner, we really seem to know more than about almost any other disease; a disease which we deliberately hunt down to its source, and stop just as we could stop the supply of stone from a quarry or of rifles from an armoury; a disease, the haunts and habits of which we know with such accuracy that we are able to go into a house and say, "Alter this, and alter that, or you will very likely get typhoid fever here," a disease the ways of which we know so well, that, when there has been a case of it caused by local defects in a house, we can almost predict what alterations are required without going to the place. Surely the results obtained from the study of this disease are some of the most striking results of sanitary progress in our day. I find that the idea has become widely spread that the recent epidemic of typhoid fever in London was due to the distribution of milk from a sewage farm; this was not so, and I regard it most in the light of a special providence that none of the milk sent out from that establishment came from a sewage farm: had it been so, such a fact, combined with the prejudice and ignorance which exists upon the matter, would have dealt a severe blow to the progress of one of the greatest sanitary improvements of the day. The cause of that epidemic is known with absolute certainty, the very channel by which the poison got into the dairy well having been recently unearthed.

I must allude, for an instant, to the recent sanitary legislation; it has been found fault with by many on account of matters of detail; but consider the fact that the result of it is that the country has spent a large sum of money in the employment of medical officers of health and sanitary inspectors, and that such men now exist, and you will see that in it we may find great cause for rejoicing when looking to the future of sanitary progress. In a lecture on the "History of Hygiene," which I delivered some three or four years ago at University College, London, I said, "From its very nature, hygiene interests all classes of society; but it is to those who are worst off—the poorest and most wretched—that it must direct its first attention. Civilisation has its evils as well as its advantages, as Bouchardat has well remarked; and one of the greatest of them is the over-crowding of people in the great centres of population, with the misery and disease which are the results of it. It is to better constructed houses for the working classes, to a free supply of good water, and to satisfactory sewerage arrangements, that we must look for an amelioration in these respects; and I would hasten to add, to a wider spread among those classes of such an education as shall lead them to appreciate the means used for the improvement of their condition, and to lend a helping hand for the furtherance of those means."

I feel that I cannot do better in conclusion than congratulate this town on having, through the munificence of one of its citizens, been the first to appreciate the importance of the education of the people in these subjects, and on having such an institution as this in which so much useful knowledge is imparted to the people, and congratulate myself on having the privilege of such an opportunity of spreading broadcast the great truths of sanitary science. The time is fast coming which was looked forward to by Dr. Parkes when he wrote:—"Let us hope that matters of such great moment may not always be considered as of less importance than the languages of extinct nations, or the unimportant facts of a dead history."

SCIENTIFIC SERIALS

THE current *Ibis* commences with the latter part of Mr. Brooke's notes on the ornithology of Sardinia, special attention being drawn to *Otis tetrax*, which is moderately common; *Phœnicopterus roseus*, which occurs in large flocks during the winter and even up to June; the presence of *P. erithacus* is doubtful. *Fulica nigrosa* was not seen, though included in both Cara's and Salvadori's lists. In the museum there are several specimens o *Phalacrocorax desmarestii*, and *P. carbo* is extremely common. *Larus andouini* is found, though very rarely.—Captain F. W. Hutton, in a note on *Rallus modestus* of New Zealand, gives evidence to show that Dr. Buller is in error when he considers *R. modestus* to be *R. dieffenbachii*, in an immature state of plumage, as the proportions of the chicks are different, and the bill of the latter more slender.—Messrs. Salvin and Elliot in continuation of their notes on the *Trochilidæ*, discuss the genus *Thalurania*, which is exclusively tropical, and consists of eleven species and five sections.—In notes on Chinese ornithology, Mr. R. Swinhoe draws special attention to *Ceryle rudis* at Ningpo, *Gallinago solitaria*, *Endrominas veredus*, and other land as well as water-birds found at Shanghai.—Mr. Sclater supplements Mr. Salvin's list of the birds of Nicaragua, with additions from a recent small collection made by Mr. Belt, adding seventeen species, mostly well known through Central America.—Mr. E. L. Layard gives notes of the birds observed in Para; and Mr. Sclater describes and figures two new species named by him *Picolaptes layardi*, and *Thamnophilus simplex*.—Captain J. H. Lloyd on the birds in the province of Kattiawar in West India, commences the detailed account with an interesting comment on the general ornithological description of the region.

THE *Monthly Microscopical Journal* for October, commences with a description, by Mr. F. H. Welch, of the thread-worm *Filaria immitis*, occasionally infesting the vascular system of the dog, with remarks on the same, relative to Haematozoa in general, and the Filaria in the human blood. The specimens described were obtained from the right ventricle and pulmonary artery of a dog, from Shanghai, the male, female, and young being described. The left ventricle also contained some of the young.—Dr. Royston-Pigott fully illustrates a paper entitled "Researches in Solar Spectra, applied to test residuary aberration in microscopes and telescopes; and the construction of a compensating eye-piece, being a sequel to the paper on a searcher for aplanatic images."—Dr. Rutherford describes a new freezing microtome in which the freezing box and escape tube are much larger than in his older instrument, and the indicator is improved.—Mr. Ch. Stodder, in a letter, points out that it is inaccurate to suppose that the nominal price of American objectives is directly comparable with that of English makers, as the value of money in the two countries is so different, and duty has to be paid on entering the former.

Annali di Chimica applicata alla Medicina, July number, 1873.—We notice in this journal, besides a number of formulæ for pharmaceutical preparations and other details interesting to the druggist, a paper by A. Gubler, on experiments with new and old opium alkaloids, which deals, amongst others, with apomorphia.—There is also a translation of Mr. Simon's memorandum on the diffusion of cholera, and other papers from native and foreign sources. In the *Rendiconto delle sessioni dell' Academia delle scienze dell' Istituto di Bologna*, 1872–1873," are given briefly (in about 189 pages) abstracts of the papers read before the Society, together with other matter of the usual nature.

Reale Istituto Lombardo di scienze e Lettre Rendiconti, Fascicolo xiii.," July 1873.—This number contains several critical literary, historical, and philosophical papers, including one on Kant's philosophy, by C. Cantoni.—In the scientific section there is a paper by Prof. Cavalleri on improvements in the helioscope, and a portion of a paper by P. Cantoni on electrical adherence, which is illustrated with several tables of data.—Fascicolo xiv. contains a paper on the capacity of the nasal fossa, by P Mantegazza, and one on cholera by G. Strambio.—C. Lombroso details some experiments on the tonic action of

maize (*guasto*) affected with the *Penicillum glaucum*. The author maintains that the maize in this state acts injuriously. G. Sangalli, who replies to the paper, maintains that the effects are due to another cause.—New comet discovered at the Royal Observatory of Milan, by G. Tempel; communicated by G. V. Schiaparelli.—The continuation of P. Cantoni's paper on electrical adherence is given.—The other papers are on the propagation of the corpuscle cornalia, by C. Gibell, and a letter on a purulent disease of one hemisphere of the brain, by L. Porta.

SOCIETIES AND ACADEMIES

Philadelphia

Academy of Natural Sciences, June 3.—Dr. Ruschenberger in the chair.—"Fertilisation of *Pedicularis canadensis*." Mr. Thomas Meehan drew attention to the structure of the flower of *Pedicularis canadensis*, in which it was evident self-impregnation was impossible, and there seemed to be no special arrangements for fertilisation by distinct agency, as there were in so many allied plants. In this case the stamens were included in the closely compressed arch of the corolla, and, with the anthers, were directed retrorsely to the pistil, which at an early stage, and long before the maturity of the pollen, was protruded beyond the corolla, rendering self-fertilisation almost impossible in this flower. But the flowers were always abundantly fertile, and though the arrangements were such as seemingly to afford no chance even for insects to aid in the fertilisation, it was also probable that in some way it was accomplished by them. Both last season and this he had devoted some time to watching the plant, but failed to find any clue to the process. A species of *Bombus* seemed to have the plant especially under its charge, visiting the flowers in great numbers; but they bored through the corolla on the outside of the tube for the saccharine matter, and the anthers or pollen did not seem to be in the least disturbed by this. Still it was so highly probable that in some way some insect aided in the cross-fertilisation of these flowers, that it might serve a useful purpose to direct attention to it, as others with time and opportunity might discover what he had failed to find.

Riga

Society of Naturalists, April 16—M. Tank communicated some observations on honeydew, which he thinks is an immediate excretion of the leaves due to cooling.—M. Behrmann gave reasons for doubting the supposition that certain fires which occurred almost daily from October to December last year, in a village of the Orel Government, arose from phosphuretted hydrogen out of the marshy ground.

April 23.—M. Petzholdt read a paper on the composition and formation of Imatra stones. Various hypotheses of formation have been given—the gyratory, the stalactitic, the geological, the vegetable, the animal, &c. Parrot supposed the stones to be petrified, shell-less molluscs. M. Petzholdt formulates his view thus:—In a slimy layer of fine sand, mud, and carbonate of lime, are formed, through mutual attraction of particles of the latter, several ball-heaps of lime. Next, dry deposition of the whole at a later epoch. Disturbance of the stratum by water, setting free the hard spherical masses (Imatra stones).

April 30.—M. Pfeiffer showed a small headless chick with large legs, found dead with another, which was alive in the same egg. The two were connected by a fibre. After separation the living chick throve normally.

May 21.—M. Glasenapp gave a note on blackened wood in certain trees blown down in a storm. The blackening is attributed to a kind of fungus which formed on the north side of the trees while yet standing.—M. Gottfriedt read a paper on enclosure of diamonds in xanthophyllite; the supposed diamonds he finds to be merely hollow spaces, erosion figures.—M. Teich gave an account of an excursion to North-West of Kurland.—The *Correspondenz Blatt*, No. 9, contains a description of the snakes of the Baltic Provinces, of which there are three species—*Vipera verus*, *Tropidonotus natrix*, and *Coronella laevis*.

Gottingen

Royal Academy of Sciences, Aug. 6.—Dr. Paul du Bois-Reymond communicated a paper on the representation of functions by Fourier's series.

Aug. 13.—M. Waitz compared some points in the Annales Sithiensis, relative to Pippin and Charlemagne, with other annals of the time.—M. Ewald gave a paper on the passage, Ezek. xlv. 12: "Twenty shekels, five-and-twenty shekels, ten-and-five shekels shall be your maneh." The maneh, it is known, originally contained 60 shekels (which these numbers make up), and this enumeration, he thinks, was in order to exactness and certainty, not because there were coins of these several values. The Septuagint version (rightly read) makes the maneh 50 shekels, and it is known there was such a maneh. The author advances a theory, on which the passage affords evidence of both manehs having been known in the first half of the sixth century B.C.—Dr. Voss communicated a note on the geometry of focal surfaces of congruences.

Aug. 20.—M. Minnigerode gave a long paper on a new method of solving Pell's Equation $t^2 D\mu = 1$.

Paris

Academy of Sciences, October 6.—M. Bertrand in the chair.—The following papers were read:—Note on the means used to obtain a constant temperature in rooms and on the methods of moderating it during the heat of summer, by General Morin.—On new propyl compounds, by M. A. Cahours. The author described several ethers of the propyl series.—Certain considerations on the yellow elastic tissue and its immediate organic analysis, by M. Chevreul.—Treatment of carbuncle and malignant pustule by carbolic acid and ammonic carbolate, by M. Déclat.—Statistical tables of the losses of German armies in France during the war of 1870–1, by Capt. D. H. Leclerc.—The subcutaneous infarctus of cholera, by M. Bouchut.—On the improvement in healthfulness caused by the growth of *Eucalyptus globulus* in marshes, by M. Gimbert.—Studies on the *Phylloxera*, by M. Max Cornu.—On the action on the vine of the carbonic disulphide used to destroy the *Phylloxera*, by M. Lecocq de Boisbaudran.—On the size and variations of the sun's diameter, by S. Respighi. The author in his letter criticised Secchi's statements as to the difference between the nautical almanac diameter and his own observations by monochromatic light. He regarded Secchi's observations as erroneous.—On the theory of the thrust of earthworks, by M. J. Curie.—On the condensation of gases and liquids by carbon, by M. Melsens. The author noticed the thermal phenomena produced by the contact of the liquids with carbon, &c.—On the production of certain borates in the dry way, by M. Ditte.—Researches on tribromacetic acid, by M. H. Gal.—On the development of *Batrachians*. This was a note on the embryos of *Hylodes martinensis*, by M. Bavay.

PAMPHLETS RECEIVED

English.—Synopsis of all the Mosses known to inhabit Ireland: David Moore, Ph.D.—Lobley's Geologist's Excursion to the Malvern District.—Proceedings of the Belfast Natural History Society for 1871–2—Leyton Astronomical Observations.—Report, Chester Society of Natural Science.—Law of Elliptic Motion deduced from the Laws of Gravitation and Compound Rotation: G. Hamilton.—Milk, Typhoid Fever and Sewage: Alfred Smee.—Contributions to the Knowledge of the Meteorology of the Antarctic Regions.—A new Method of obtaining the Differentials of Functions; Profs. Rice and Johnson.—Count Rumford, How he Banished Beggary from Bavaria: T. L. Nichols, M.D.—A Scamper across Europe: T. L. Nichols, M.D.

CONTENTS

LOCAL SCIENTIFIC SOCIETIES

I.

WE have devoted part of our space this week to a kind of Census of our Local Scientific Societies. It will be seen that in these Islands we already muster a goodly number, but no friend of Science would consider the number satisfactory; it does not, we are sure—seeing that there are twenty counties in England and Wales, and a much larger proportion in Scotland and Ireland, which appear not to boast of any such society—represent the true activity of the different regions from which, so to speak, the societies are fed. We do not suppose that our list is accurate; indeed our present purpose in printing it is to gather information. We hope that many societies exist which are not in our list; we fear that some have already ceased to exist since the time that Sir Walter Elliot, with infinite pains, compiled some of the data on which we have had to rely in the absence of information forwarded by the officers of the societies themselves.

On the whole, however, all lovers of Science and advocates for the spread of scientific education among all classes, ought to feel greatly gratified at the rapid increase during recent years, of local scientific societies and field-clubs indicated by the dates of foundation to be found in our list. No more unmistakeable sign of a general elevation of taste, of the spread of the scientific influence and of a desire for scientific knowledge, can, we think, be obtained, than this starting-up, in all parts of the country, of societies for the express purpose of scientific work in one form or another, and that generally as a means of recreation. By far the greater number of the societies have had their birth within recent years. With one or two exceptions, the older societies are not very prominenly scientific, while as a rule the recently founded ones bear on their very front the declaration that they have been established solely for the pursuit of Science.

This is indeed very encouraging, more especially when we reflect that this result is no outcome of any temporary burst of enthusiasm, of any exciting scientific "revival" agitation, but is simply the natural fruit of the slow but sure development of the scientific spirit in our country.

From the information which has been kindly sent us by the secretaries of the various societies many interesting facts might be presented, and many curious and valuable inferences drawn. It will be seen from the list, that the societies are very unequally distributed over the country, quite a busy hive of them being clustered around the border counties of England and Scotland, while not a few counties in both countries, as well as in Ireland, are quite unrepresented, and many large counties by but a single society. Why should this be? Is it to be attributed to the backward state of intelligence and education in the unrepresented districts? We do not think so; we believe that in every county in the three kingdoms, men and women will be found with an intelligent love of Science, a desire for scientific knowledge, and a wish for the spread of scientific education. Such people only require to be roused to perceive the advantages of the establishment of scientific societies and field-clubs in their midst; if only some one would take the initiative and start such societies where they do not at present exist, we have no fear, if judicious means be used, that ample success will follow. From the large number of members belonging to many of the societies members belonging to all classes of society, it will be seen that it is now considered honourable to be connected with such an association; and although in most societies there is only a small nucleus of working members, still while efforts should be made to engage all in the work, the non-working majority should be considered as, at least by their subscriptions and good-will, they help on the good cause.

Into these and other details we hope to enter in one or more future articles, founded partly on the statistics we possess. At the present time, when a Committee of the British Association is considering the whole question of our local Societies, we think it useful to point out the extreme importance of an increased activity in this direction. The recent action of the Government in aiding the establishment of Science Schools has enormously increased the advantages which such local associations may confer on outsiders, while at the same time it has greatly widened the recruiting ground. And it is in this double capacity that the formation, encouragement, and extension of such societies should be the care of all, whether scientific in their tastes or not; while, to friends of Science it is crucial, for Government aid, under existing arrangements, can only come where there are Science Classes; and without Government aid, in nine cases out of ten, the thing will fall to the ground altogether, or drag on an existence of second-rate utility.

If there then be any Scientific Societies without Science Classes attached to them, let them be assured that their museums are comparatively valueless; and further, that their museum must always remain as it is, for though it is clear to many that the Government must soon supply typical collections to museums which are available for teaching purposes, it is equally clear that there is no reason why they should do so to museums the utility of which is limited merely to members of a society.

Again: If there be any Scientific Societies without Science Classes attached to them let them be assured that their courses of lectures will prove of the least possible value; for mere lectures to those anxious to learn, but who are debarred from more serious study, are more than disappointing, they are hurtful.

In the ordinary course of things the Lecture should be the precursor of the Science Class. The Science Class should drive the student to the Museum, and from the zealous students the society should be recruited.

There is one point in which all will acknowledge our local societies have of late made considerable progress, and here again the British Association has been helpful to them—we refer to the more general establishment of courses of lectures, and the more general engagement of competent men of science, to place things new and strange before their members. Let not such lecturers forget that their duty is almost a sacred one; though he may not be a Davy, there may yet be a Faraday among the audience, one who may be gained or lost to Science according as the lecturer does his allotted work well or ill.

This brings us to another point. Why should not physical and chemical apparatus available for high-class experimental lectures be occasionally seen in our museums or in rooms adjoining them? Why should the stuffed crocodile and curious weapon of some

southern race of savages have it all their own way to the extent that they do? Here, no doubt, our Government has been greatly at fault, for after all, humble local museums, *parvis componere magna*, are little British Museums, and there is no help provided by the government for any physical, or chemical, or astronomical students in the British Museum. But though our government is behind the age in London, the South Kensington authorities are alive to the weak point in the armour, as regards the provinces, and if a local society will only establish a Science Class, travelling collections of the most important modern scientific instruments are to be had for the asking; and we may hope that ere long there may be a model museum at South Kensington, doing for physical science what is done for it in Paris by the magnificent *Conservatoire des Arts et Métiers*, a museum in which the applications of Science, and the implements for the teaching of Science hold the first place.

FARADAY ON SCIENTIFIC LECTURING

AT a time when the lecture season is commencing, we believe we shall be doing good service by placing before those of our readers who are not already acquainted with them in Dr. Bence Jones' "Life of Faraday," the opinions of that great man on many points connected with lectures on Science.

They were written to a friend when Faraday was but 21 years of age, but we believe he would have changed little though he might have added much if he had revised them in his later years. He commences by explaining that:—

"The subject upon which I shall dwell more particularly at present has been in my head for some considerable time, and it now bursts forth in all its confusion. The opportunities that I have latterly had of attending and obtaining instructions from various lecturers in their performance of the duty attached to that office, has enabled me to observe the various habits, peculiarities, excellencies, and defects of each of them as they were evident to me during the delivery. I did not wholly let this part of the things occurrent escape my notice, but when I found myself pleased, endeavoured to ascertain the particular circumstance that had affected me; also, whilst attending Mr. Brand and Mr. Powell in their lectures, I observed how the audience were affected, and by what their pleasure and their censure were drawn forth.

"On going to a lecture I generally get there before it begins; indeed, I consider it as an impropriety of no small magnitude to disturb the attention of an audience by entering amongst them in the midst of a lecture, and, indeed, bordering on an insult to the lecturer. By arriving there before the commencement, I have avoided this error, and have had time to observe the lecture-room."

He dwells on the form of the lecture-room, and then indicates how important a matter ventilation is.

"There is another circumstance to be considered with respect to a lecture-room of as much importance almost as light itself, and that is ventilation. How often have I felt oppression in the highest degree when surrounded by a number of other persons, and confined in one portion of air! How have I wished the lecture finished, the lights extinguished, and myself away merely to obtain a fresh supply of that element! The want of it caused the want of attention, of pleasure, and even of comfort, and not to be regained without its previous admission. Attention to this is more particularly necessary in a lecture-room intended for night delivery, as the lights burning add considerably to the oppression produced on the body."

He then goes on:—

"Having thus thrown off, in a cursory manner, such thoughts as spontaneously entered my mind on this part of the subject, it appears proper next to consider the subject fit for the purposes of a lecture. Science is undeniably the most eminent in its fitness for this purpose. There is no part of it that may not be treated of, illustrated, and explained with profit and pleasure to the hearers in this manner. The facility, too, with which it allows of manual and experimental illustration, places it foremost in this class of subjects. After it come (as I conceive) arts and manufactures, the polite arts, belles lettres, and a list which may be extended until it includes almost every thought and idea in the mind of man, politics excepted. I was going to add religion to the exception, but remembered that it is explained and laid forth in the most popular and eminent manner in this way. The fitness of subjects, however, is connected in an inseparable manner with the kind of audience that is to be present, since excellent lectures in themselves would appear absurd if delivered before an audience that did not understand them. Anatomy would not do for the generality of audiences at the R. I. (Royal Institution), neither would metaphysics engage the attention of a company of schoolboys. Let the subject fit the audience, or otherwise success may be despaired of."

Now for the lecturer:—

"A lecturer may consider his audience as being polite or vulgar (terms I wish you to understand according to Shuffleton's new dictionary), learned or unlearned (with respect to the subject), listeners or gazers. Polite company expect to be entertained not only by the subject of the lecture, but by the manner of the lecturer; they look for respect, for language consonant to their dignity, and ideas on a level with their own. The vulgar—that is to say in general, those who will take the trouble of thinking, and the bees of business—wish for something that they can comprehend. This may be deep and elaborate for the learned, but for those who are as yet tyros and unacquainted with the subject must be simple and plain. Lastly, listeners expect reason and sense, whilst gazers only require a succession of words.

"These considerations should all of them engage the attention of the lecturer whilst preparing for his occupation, each particular having an influence on his arrangements proportionate to the nature of the company he expects. He should consider them connectedly, so as to keep engaged completely during the whole of the lecture the attention of his audience.

"I need not point out to the active mind of my friend the astonishing disproportion, or rather difference, in the perceptive powers of the eye and the ear, and the facility and clearness with which the first of these organs conveys ideas to the mind—ideas which, being thus gained, are held far more retentively and firmly in the memory than when introduced by the ear. 'Tis true the ear here labours under a disadvantage, which is that the lecturer may not always be qualified to state a fact with the utmost precision and clearness that language allows him and that the ear cannot understand, and thus the complete action of the organ, or rather of its assigned portion of the sensorium, is not called forth; but this evidently points out to us the necessity of aiding it by using the eye also as a medium for the attainment of knowledge, and strikingly shows the necessity of apparatus.

"Apparatus, therefore, is an essential part of every lecture in which it can be introduced; but to apparatus should be added, at every convenient opportunity, illustrations that may not perhaps deserve the name of apparatus and of experiments, and yet may be introduced with considerable force and effect in proper places. Diagrams, and tables too, are necessary, or at least add in an

eminent degree to the illustration and perfection of a lecture. When an experimental lecture is to be delivered, and apparatus is to be exhibited, some kind of order should be observed in the arrangement of them on the lecture table. Every particular part illustrative of the lecture should be in view, no one thing should hide another from the audience, nor should anything stand in the way of or obstruct the lecturer. They should be so placed, too, as to produce a kind of uniformity in appearance. No one part should appear naked and another crowded, unless some particular reason exists and makes it necessary to be so. At the same time, the whole should be so arranged as to keep one operation from interfering with another. If the lecture-table appears crowded, if the lecturer (hid by his apparatus) is invisible, if things appear crooked, or aside, or unequal, or if some are out of sight, and this without any particular reason, the lecturer is considered (and with reason too) as an awkward contriver and a bungler.

"The most prominent requisite to a lecturer, though perhaps not really the most important, is a good delivery; for though to all true philosophers science and nature will have charms innumerable in every dress, yet I am sorry to say that the generality of mankind cannot accompany us one short hour unless the path is strewed with flowers. In order, therefore, to gain the attention of an audience (and what can be more disagreeable to a lecturer than the want of it ?), it is necessary to pay some attention to the manner of expression. The utterance should not be rapid and hurried, and consequently unintelligible, but slow and deliberate, conveying ideas with ease from the lecturer, and infusing them with clearness and readiness into the minds of the audience. A lecturer should endeavour by all means to obtain a facility of utterance, and the power of clothing his thoughts and ideas in language smooth and harmonious, and at the same time simple and easy. His periods should be round, not too long or unequal; they should be complete and expressive, conveying clearly the whole of the ideas intended to be conveyed. If they are long, or obscure, or incomplete, they give rise to a degree of labour in the minds of the hearers which quickly causes lassitude, indifference, and even disgust.

"With respect to the action of the lecturer, it is requisite that he should have some, though it does not here bear the importance that it does in other branches of oratory; for though I know of no species of delivery (divinity excepted) that requires less motion, yet I would by no means have a lecturer glued to the table or screwed on the floor. He must by all means appear as a body distinct and separate from the things around him, and must have some motion apart from that which they possess.

"A lecturer should appear easy and collected, undaunted and unconcerned, his thoughts about him, and his mind clear and free for the contemplation and description of his subject. His action should not be hasty and violent, but slow, easy, and natural, consisting principally in changes of the posture of the body, in order to avoid the air of stiffness or sameness that would otherwise be unavoidable. *His whole behaviour should evince respect for his audience, and he should in no case forget that he is in their presence.* No accident that does not interfere with their convenience should disturb his serenity, or cause variation in his behaviour; he should never, if possible, turn his back on them, but should give them full reason to believe that all his powers have been exerted for their pleasure and instruction.

"Some lecturers choose to express their thoughts extemporaneously immediately as they occur to the mind, whilst others previously arrange them, and draw them forth on paper. Those who are of the first description are certainly more unengaged, and more at liberty to attend to other points of delivery than their pages; but as every person on whom the duty falls is not equally competent for the prompt clothing and utterance of his matter, it becomes necessary that the second method should be resorted to. This mode, too, has its advantages, inasmuch as more time is allowed for the arrangement of the subject, and more attention can be paid to the neatness of expression.

"But although I allow a lecturer to write out his matter, I do not approve of his reading it; at least, not as he would a quotation or extract. He should deliver it in a ready and free manner, referring to his book merely as he would to copious notes, and not confining his tongue to the exact path there delineated, but digress as circumstances may demand or localities allow.

"A lecturer should exert his utmost effort to gain completely the mind and attention of his audience, and irresistibly to make them join in his ideas to the end of the subject. He should endeavour to raise their interest at the commencement of the lecture, and by a series of imperceptible gradations, unnoticed by the company, keep it alive as long as the subject demands it. No breaks or digressions foreign to the purpose should have a place in the circumstances of the evening; no opportunity should be allowed to the audience in which their minds could wander from the subject, or return to inattention and carelessness. A flame should be lighted at the commencement, and kept alive with unremitting splendour to the end. For this reason I very much disapprove of breaks in a lecture, and where they can by any means be avoided, they should on no account find place. If it is unavoidably necessary, to complete the arrangement of some experiment, or for other reasons, leave some experiments in a state of progression, or state some peculiar circumstance, to employ as much as possible the minds of the audience during the unoccupied space—but, if possible, avoid it.

"Digressions and wanderings produce more or less the bad effects of a complete break or delay in a lecture, and should therefore never be allowed except in very peculiar circumstances; they take the audience from the main subject, and you then have the labour of bringing them back again (if possible).

"For the same reason (namely that the audience should not grow tired), I disapprove of long lectures; one hour is long enough for anyone, nor should they be allowed to exceed that time.

"A lecturer falls deeply beneath the dignity of his character when he descends so low as to *angle for claps*, and *asks for commendation*. Yet have I seen a lecturer even at this point. I have heard him causelessly condemn his own powers. I have heard him dwell for a length of time on the extreme care and niceness that the experiment he will make requires. I have heard him hope for indulgence when no indulgence was wanted, and I have even heard him declare that the experiment now made cannot fail from its beauty, its correctness, and its application, to gain the approbation of all. Yet surely such an error in the character of a lecturer cannot require pointing out, even to those who resort to it; its impropriety must be evident, and I should perhaps have done well to pass it.

"Before, however, I quite leave this part of my subject, I would wish to notice a point in some manner connected with it. In lectures, and more particularly experimental ones, it will at times happen that accidents or other incommoding circumstances take place. On these occasions an apology is sometimes necessary but not always. I would wish apologies to be made as seldom as possible, and generally, only when the inconvenience extends to the company. I have several times seen the attention of by far the greater part of the audience called to an error by the apology that followed it.

"An experimental lecturer should attend very carefully to the choice he may make of experiments for the illus-

tration of his subject. They should be important, as they respect the science they are applied to, yet clear, and such as may easily and generally be understood. They should rather approach to simplicity, and explain the established principles of the subject, than be elaborate and apply to minute phenomena only. I speak here (be it understood) of those lectures which are delivered before a mixed audience, and the nature of which will not admit of their being applied to the explanation of any but the principal parts of a science. If to a particular audience you dwell on a particular subject, still adhere to the same principle, though perhaps not exactly to the same rule. Let your experiments apply to the subject you elucidate, do not introduce those which are not to the point.

"Though this last part of my letter may appear superfluous, seeing that the principle is so evident to every capacity, yet I assure you, dear A., I have seen it broken through in the most violent manner—a mere alehouse trick has more than once been introduced in a lecture, delivered not far from Pall Mall, as an elucidation of the laws of motion.

"Neither should too much stress be laid upon what I would call small experiments, or rather illustrations. It pleases me well to observe a neat idea enter the head of a lecturer, the which he will immediately and aptly illustrate or explain by a few motions of his hand—a card, a lamp, a glass of water, or any other thing that may be by him; but when he calls your attention in a particular way to a decisive experiment that has entered his mind, clear and important in its application to the subject, and then lets fall a card, I turn with disgust from the lecturer and his experiments. 'Tis well, too, when the lecturer has the ready wit and the presence of mind to turn any casual circumstance to an illustration of his subject. Any particular circumstance that has become table-talk for the town, any local advantages or disadvantages, any trivial circumstance that may arise in company, give great force to illustrations aptly drawn from them, and please the audience highly, as they conceive they perfectly understand them.

"Apt experiments (to which I have before referred) ought to be explained by satisfactory theory, or otherwise we merely patch an old coat with new cloth, and the whole (hole) becomes worse. If a satisfactory theory can be given, it ought to be given. If we doubt a received opinion, let us not leave the doubt unnoticed, and affirm our own ideas, but state it clearly, and lay down also our objections. If the scientific world is divided in opinion, state both sides of the question, and let each one judge for himself, by noticing the most striking and forcible circumstances on each side. Then, and then only, shall we do justice to the subject, please the audience, and satisfy our honour, the honour of a philosopher."

We trust that during the ensuing session, these opinions of Faraday may be in the minds of every lecturer on Science.

ECKER'S "CONVOLUTIONS OF THEB RAIN"

On the Convolutions of the Human Brain. By Dr. Alexander Ecker, Professor of Anatomy and Comparative Anatomy in the University of Freiburg, Baden. Translated, by permission of the author, by John C. Galton, M.A., Oxon., M.R.C.S., F.L.S., &c., &c. Translator of Prof. Roser's "Manual of Surgical Anatomy," &c. (London: Smith, Elder, & Co., 1873.)

OF late years the topographical anatomy of the surface of the brain has deservedly attracted considerable attention; and the recent able investigations of Hughlings Jackson and Ferrier have shown the importance, in fact the absolute necessity of a correct and generally recognised description and enumeration of the cerebral convolutions. Mr. Galton therefore deserves the thanks of all interested in the subject, for having introduced to us in English dress this valuable monograph by Prof. Ecker of Freiburg.

There are two methods by which the complex human brain may be analysed and reduced to its simpler elements, two paths that lead to the same goal; the one is by a careful examination and comparison of the brains of the lower animals, and especially of apes, which latter in their higher groups present a "sketch map" as it were, which is filled in and completed in man only. This has been carried out with great success by Gratiolet primarily, and in England it has been followed amongst others by Huxley, Marshall, Flower and Rolleston. The other method is by tracing the development of the fœtal brain, and observing which fissures, and therefore which convolutions, are the first to make their appearance, and so are of primary importance, and how these subsequently undergo farther evolution and complication. Tiedemann and Reichert have hitherto been our authorities on this point, and it is by this method chiefly that Prof. Ecker arrives at his conclusions.

In this country the admirable little treatise of Prof. Turner has been welcomed and the classification therein adopted is now generally accepted, and taught in several of our anatomical schools. Prof. Ecker in the main follows Prof. Turner, although the nomenclature, of course, is that of the German school, and so differs occasionally from ours, which follows rather Gratiolet and the French school. The synonyms are, however, in all cases faithfully given.

The author insists upon the essential difference between the Sylvian fissure and the other sulci, these being mere indentations of the cortex, whilst that is formed by the folding of the temporo-sphenoidal lobe on the fore part of the brain during its development. The anterior or ascending branch of this fissure is here correctly described as being short and arrested by the hinder end of the lower frontal convolution, whilst that described as such by Prof. Turner is a distinct sulcus (præcentral) terminating close behind the ascending ramus. The gyrus connecting the inferior and ascending frontal (anterior central) convolutions is always present, although it is not always superficial, being occasionally concealed by the over-lapping of those convolutions. Instead of the orbital lobule usually described on the under surface of the frontal lobe, the three frontal convolutions are traced round the apex to the orbital surface. The narrow ridge internal to the olfactory sulcus (gyrus rectus) is regarded as the continuation of the first, the gyrus between that and the orbital sulcus as the second, and outside the last as the third. We should rather consider all internal to the orbital sulcus as first frontal, which is grooved by a special olfactory sulcus, and the second as ending posteriorly between the anterior branches of the triradiate orbital sulcus. The marginal convolution is regarded as simply the inner surface of the superior frontal.

In the parietal lobe the supra-marginal and angular convolutions are amongst the most difficult in the brain to indicate and circumscribe. Prof. Ecker describes the

supra-marginal convolution as arching over the end of the fissure of Sylvius and joining the upper temporo-sphenoidal convolution, and the angular as folding over the hinder end of the parallel fissure and joining the middle temporo-sphenoidal convolution. This description, and it is supported by our experience, is not quite in accordance with that of some other anatomists; for instance, in Mr. Marshall's well-known essay on the brain of the bushwoman, the supra-marginal convolution is correctly defined thus, whilst the angular would require the anterior enlarged portion of the third annectent gyrus, as marked in the figure, to complete its bend and unite it to the second temporal gyrus. Similarly, in the idiot boy's brain, the angular gyrus would be a large folded convolution, there indicated as the bifurcated anterior extremity of the second annectent convolution; and in the idiot woman the parallel fissure extends so far back that it quite cuts off the angular gyrus from the temporo-sphenoidal, and the convolution is represented by the straight, also bifurcated fore part of the second annectent gyrus in the figure. The intra-parietal fissure of Turner is here called less correctly inter-parietal.

In the occipital lobe, a tolerably constant transverse depression, into which the intra-parietal fissure often debouches is appropriately named "occipital sulcus." Prof. Ecker regards the bridging, or annectent convolutions, as unworthily distinguished by special names in the human brain, since they do not bridge over any fissure as in the lower apes. He carefully points out their homology with those gyri in the ape, yet deprecates the transference of the names from the Simian to the human brain. But this comparison and correspondence of nomenclature is precisely what we require for the satisfactory determination of the cerebral functions, and the homological significance of a part is quite sufficient to justify the application of the same name to it. So also, on the inner surface, the lower annectent gyrus is described as the "gyrus cunei," and the occasional presence of the upper annectent gyrus is alluded to, of which we have now seen several examples. The operculum of the ape's brain is discussed, but the same term is unfortunately here applied to quite a different part of the human brain, viz. the united lower ends of the ascending frontal and parietal convolutions which overhang the island of Reil.

The middle convolution on the under surface of the occipito-temporal lobes is regarded, not without precedent, as the direct continuation of the gyrus fornicatus, and the uncinate gyrus of Huxley thus comes to be divided into three parts, the "lingual lobule" behind the union of the two gyri, the "convolution of the Hippocampus" immediately below the dentate fissure, and the recurved hook or "uncinate lobule"; but the connection between the gyrus fornicatus and this convolution is small and narrow, whilst that between it and the lingual lobule is large and direct; further, the author points out, after Gratiolet, that in many apes the calcarine is prolonged into the dentate fissure and cuts off the arched from the uncinate gyrus; surely this shows the essential unity of the uncinate convolution, and that the junction with the gyrus fornicatus is a superadded and secondary element in the human and certain Simian brains.

The translator has generally performed his work well; there are, however, one or two slips; for instance, the dentate fissure is said to produce an eminence in the floor of the *posterior* corner of the lateral ventricle; the parieto-occipital fissure also is described correctly as being concave forwards, whilst in the diagram it is represented as convex: the figures are exceedingly clear. Prefixed is an exhaustive bibliography by the translator, which adds materially to the value of the work; and finally, we can cordially recommend it as an accurate and lucid guide to a somewhat difficult study.

OUR BOOK SHELF

The Zoological Record for 1871. Edited by Prof. Newton. (J. Van Voorst, 1873.)

THE birth of true biological science is of so recent origin, and its development has been so rapid that until lately many of the necessary steps in the furtherance of its proper progress have remained beyond the cognizance of its most enthusiastic followers. The difficulties connected with, and the unmanageableness of the large number of facts accumulated day by day on all branches of zoology, and recorded by observers in all parts of the civilised world, have until lately been scarcely realised. Only by those who, from the disappointment which they have experienced on finding that observations which have cost them incalculable time and labour, have been previously undertaken and exhausted by others before them, either in their own or some other country, appreciate fully the necessity for an easily accessible, accurate, and not over ponderous account of the labours of previous workers.

It is only the full appreciation of the advantage to future science students which stimulates the authors of the several parts of the work before us to continue and commence their contributions to this, what may be truly termed, labour of love. The labour involved in obtaining a complete and condensed account of the gist of each zoological paper published here or elsewhere throughout a year, is so great, and the smallness of the class who are disposed to purchase the work when produced, so necessarily restricted, that at first sight it is evident that it is only with the assistance of donations from scientific bodies, or from contributions of one kind or another on the part of amateurs in the subject, that the necessary expenses can be covered and the staff maintained.

These considerations will recommend this valuable work to the consideration of all interested in zoological progress.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

On the Equilibrium of Temperature of a Gaseous Column subjected to Gravity

SINCE reading Principal Guthrie's first letter on this subject (vol. viii. p. 67), I have thought of several ways of investigating the equilibrium of temperature in a gas acted on by gravity. One of these is to investigate the condition of the column as to density when the temperature is constant, and to show that when this is fulfilled the column also fulfils the condition that there shall be no upward or downward transmission of energy; or, in fact, of any other function of the masses and velocities of the molecules. But a far more direct and general method was suggested to me by the investigation of Dr. Ludwig Boltzmann* on the final distribution of energy in a finite system of elastic bodies. A sketch of this method as applied to the simpler case of a number of molecules so great that it may be treated as infinite, will be found on p. 535. Principal Guthrie's second letter (vol. viii. p. 486) is especially valuable as stating his case in the form of distinct propositions, every one or

* Studien über das gleichgewicht der lebendigen Kraft zwischen bewegten materiellen Punkten. Von Dr. Ludwig Boltzmann. Sitzb. d. Akad. d. Wissensch, October 8, 1868 (Vienna).

which, except the fifth, is incontrovertible. He has himself pointed out that it is here that we differ, and that this difference may ultimately be traced to a difference in our doctrine as to the distribution of velocity among the molecules in any given portion of the gas. He assumes, as Clausius, at least in his earlier investigations, did, that the velocities of all the molecules are equal, whereas I hold, as I first stated in the *Phil. Mag.* for Jan. 1860, that they are distributed according to the same law as errors of observation are distributed according to the received theory of such errors.

It is easy to show that if the velocities are all equal at any instant they will become unequal as soon as encounters of any kind, whether collisions or "perihelion passages" take place. The demonstration of the actual law of distribution was given by me in an improved form in my paper on the Dynamical Theory of Gases, "Phil. Trans." 1866, and *Phil. Mag.* 1867, and the far more elaborate investigation of Boltzmann has led him to the same result. I am greatly indebted to Boltzmann for the method used in the latter part of the sketch of the general investigation (see p. 535) which was communicated in a condensed form to the British Association on Sept. 20, 1873.

J. CLERK-MAXWELL

Mallet-Palmieri's Vesuvius

As I am assured that it would be most undesirable as well as unbecoming of me to continue a scientific controversy in the tone of Mr. Mallet's letter which appeared in NATURE of October 9, I would only beg those who have perused it to remember that my remarks were altogether directed to the assertions contained in Mr. Mallet's introductory sketch, and not comments upon his theory of volcanic energy of which, as he himself admits, we as yet know little or nothing. I would then ask them to compare its contents with the substance of my letter in NATURE, Sept. 4, and judge for themselves whether so far from its being any answer to my arguments, it does not, on the contrary, furnish additional "evidence of his confounding chemical constitution with percentage composition, &c.," the very keynote of this discussion.

Mr. Mallet writes—"Mr. Forbes appears to think that chemists, mineralogists, and geologists are the sole arbiters" of such questions; a remark he could not have made had he read some of my publications; yet I am quite willing to admit that I do place more faith in them collectively, than in any one physicist or mere mechanician whether theoretical or practical; and I believe I am correct in asserting that no theory of volcanoes will be accepted by the scientific world until its doctrines are proved to be fully in accordance with the facts brought forward by these sciences.

When the reasons for my delay in answering Mr. Mallet's criticisms were fully stated, is it not, to say the least, most unjust of him to harp on this string, after having already taken more than a month to produce a rejoinder the reverse of an answer, and the style of which, peculiar to himself, is in complete harmony with that of his introductory sketch, of which one of his favourable reviewers writes—"We do not cordially approve of his method of dealing with other writers. There is, if we may be excused the expression, a tone of bitterness all through his writing which gives the reader a most uncomfortable sensation, and leads a person altogether unbiassed to imagine a feeling of jealousy on the part of so distinguished a writer as Mr. Mallet which we are sure cannot exist in reality. After giving a sketch of the various authors who have ventured to give different and erroneous opinions on the subject of vulcanicity," &c. Another reviewer remarks that—"While objecting to most of the views of geologists, which, however, he frequently distorts, Mr. Mallet claims the character of physical truth for his own ideas," and adds, "what we chiefly object to in this portion of the volume is the assumption on Mr. Mallet's part of a conscious superiority to others, and a freely expressed contempt for all previous observers, especially for geologists." Need I add more?

Oxford Science Fellowships

As Mr. Perry's letter, in the last number of NATURE, contains assertions calculated to impede the progress of science here by deterring persons, not graduates of Oxford, from competing for appointments in colleges, and also involves charges of, to say the least, discourtesy to himself, I trust you will find space in your next number for the following explanation.

First, as to Mr. Perry's general assertion respecting fellowships. From the fact that a graduate of Belfast is ineligible for a Fellowship in *Merton College*, Mr. Perry infers that "outsiders are ineligible for *Oxford* Fellowships in Physical Science." This is clearly illogical, and it is also untrue.

Secondly, as to the special case of Mr. Perry.

The ordinances of Merton College state that "no person shall be eligible" for a fellowship "who shall not have passed all the examinations required by the University for the degree of Bachelor of Arts." It appears a possible interpretation that Cambridge and Dublin B.A.'s, who can at any time incorporate in this University, may be candidates. If this be so, the reply of the Warden of Merton, as Mr. Perry gives it (of the actual correspondence I know nothing), may be correct, though perhaps not sufficiently explicit. This, however, is a legal question, and the college is taking steps to obtain the opinion of an eminent counsel.

Mr. Perry was not left, as his letter would naturally lead readers to infer, without warning as to this difficulty; for in July I wrote to Mr. Perry strongly expressing my doubt as to his eligibility, but as I was away from Oxford I could not quote the words of the ordinance; I advised him to consult the sub-warden, but I believe he did not follow my advice.

Mr. Perry received my letter, and replied to it on July 27.

The great difficulties which Mr. Perry asserts to have been thrown in his way, simply arose from the fact that he only proposed to come to Oxford during the vacation. Now it is not to be expected that I should allow any person who chooses to apply to overhaul the physical apparatus of the University in my absence, and it is unreasonable to suppose that, to suit the convenience of such a person, I must give up engagements made long before, in order to assist him in a candidature for an office of emolument in a college.

It must be borne in mind that there are nineteen colleges, any one of which may at any time offer a fellowship for proficiency in physics, and consequently to have to be at the service of outsiders, who may wish to be candidates, during the long vacation (the only time I have for real study) might become a serious matter, and to ask for such assistance seems to me to make a most unreasonable request.

I must add that if Mr. Perry imagines he would have been at any appreciable disadvantage by not knowing the particular instruments in the University cabinet (which it is by no means certain would be used for a college examination), either he assumes that the examiners would be guilty of the absurdity and unfairness of puzzling candidates by new or peculiar apparatus, or he feels very uncertain about his own practical knowledge.

A Cambridge B.A. is a candidate for the Merton Fellowship, and I have every reason to think that he found the Oxford candidates on exactly equal terms with himself in the practical examination.

H. B. CLIFTON

Oxford, Oct. 18

P.S.—Since writing the above I have been informed that a Cambridge graduate has been elected to a Science Fellowship in Magdalen College, Oxford. This is a proof of the inaccuracy of Mr. Perry's statement as to the ineligibility of outsiders for Oxford Fellowships.

Harmonic Echoes

I BELIEVE the echo observed by W. J. M. is of a different nature from mine and more analogous to one described by Oppel (Pogg. Ann. xciv. 357, 530). Each bar of the railing, when struck by the aërial pulse, diverts a small portion, which is scattered in all directions, much as if the bar were itself the source of sound. These derived pulses reach the ear of the observer at approximately equal intervals, and accordingly blend into a musical note, whose pitch, however, may not be quite constant. Oppel discusses the effect of different positions of the original source and the observer with respect to the grating, on which alone the pitch and its variations depend. It is evident that an echo formed in this way is in no sense *selective*.

I have been asked several times how the Bedgebury echo would be affected by the *character* of the original sound. Of course, if my theory is correct, the octave could not be returned, unless it were originally present; but the intensity of the echo was too feeble to give any promise of a successful observation with such an instrument as the clarinet. The experiment would be most interesting if a more powerful echo of the same class can be found.

Deep-sea Soundings and Deep-sea Thermometers

We feel sure you will not deny us space in your valuable periodical, when we tell you that, however unconsciously on your part, you, as well as other scientific authorities, are the means of doing us injustice and much professional injury, by the frequent allusions to the so-called Casella-Miller Thermometer, now used in deep-sea investigations. We are certain that we have only to call your attention to the real facts of the case for you to set the matter right before your readers.

1. We beg to state that in the year 1857 we invented, made, and supplied the Meteorological Department of the Board of Trade with upwards of fifty instruments of this description.

2. This thermometer we called the Double Bulb Deep Sea Thermometer, and a notice of it was published in the first number of the Meteorological Papers for the year 1857.

3. This thermometer, identical in every respect (except in its size), has been, after a lapse of some twelve years, *re-invented* and ushered before the scientific world with all the prestige of having a paper read upon it by the Vice-President of the Royal Society, Dr. Miller, who declared that he had just invented the instrument, in which task (of inventing an instrument well-known to all leading instrument makers, and Mr. Casella among the number) the learned doctor says he was assisted by Mr. Casella. (See Proceedings of the Royal Society, No. 113, page 482).

4. Annexed is an extract from Dr. Miller's paper describing the instrument, and by its side we give an extract from a treatise published by us in the year 1864, called "A Treatise on Meteorological Instruments."

Extract from "The Proceedings of the Royal Society," vol. xvii. page 483. Paper read June 3, 1869, by Dr. Miller.	Extract from "Negretti and Zambra's Treatise on Meteorological Instruments," published 1864, page 90:—
"The expedient adopted for protecting the thermometer from the effects of pressure consisted simply in enclosing the bulb of such a Six's thermometer in a second or outer glass tube, which was fused upon the stem of the instrument. "This outer glass tube was nearly filled with alcohol, leaving a little space to allow of variation in bulk due to expansion. "The spirit was heated to displace part of the air by means of its vapour, and the outer tube and its contents were sealed hermetically."	"The usual Six's thermometers have a central reservoir or cylinder containing alcohol. This reservoir, which is the only portion of the instrument likely to be affected by pressure, has been in Negretti and Zambra's new instrument superseded by a strong outer cylinder of glass containing mercury and rarefied air; by this means the portion of the instrument susceptible of compression has been so strengthened that no amount of pressure can possibly make the instrument vary."

5. We leave your readers to draw their own conclusions as to the similarity of the two instruments. Dr. Miller, when we called his attention to the fact of our prior claim, stated that he was not aware of the existence of our instrument, and we freely acquit Dr. Miller of conscious plagiarism, but we cannot omit to state, at the same time, that at the date at which Dr. Miller's paper was read, any scientific instrument maker worthy of the name was fully acquainted with our arrangement.

6. In order to prove what we thought of our instruments and as to their fitness for the purpose they were intended, when we were written to by the Meteorological Committee, three or four years ago, to produce a thermometer to be submitted to them for approval, we replied that we had already produced the only thermometer which in our opinion would answer the purpose, and that the thermometer was well known to them; we also said we were ready to make that instrument smaller, or larger, but that we could not possibly produce a better one.

Settle Caves Report

In your abstract of the "Report of the Committee for exploring the Victoria Cave at Settle, by W. Boyd Dwakins, F.R.S." vol. viii. p. 476, are the following sentences. "The exact age of the Cave-earth is a matter of dispute. Mr. Tiddeman from the *physical evidence alone* regards it as preglacial, or rather as older than the great ice-sheet of that district."

Now it is true that in the spring of 1871, at a meeting of the Settle Caves Committee, I suggested the probability of the beds of lower Cave-earth in the Victoria Cave being of preglacial age from the physical evidence in the cave alone; but at a committee meeting at Settle soon after I laid much stress upon the impossibility of any animals, existing before the time of the Ice-sheet, having their remains preserved in the open country, although it was very likely that they might be found sealed up in sheltered caves. Acting on this idea the committee, notwithstanding some opposition, fortunately determined upon continuing their researches, and the result was the interesting discovery of the older mammals

May I be permitted to cite the following paragraph from the *Geological Magazine* of Jan. 1873, to show that I do not rely upon the physical evidence in the cave alone as determining the age of the lower cave-earth, although I confess that evidence, to my mind, is almost conclusive. "Perhaps one of the strongest pieces of evidence that the older cave mammals mentioned lived in this district only at a time previous to the great ice-sheet is, that so far as we know the remains of none of them (except of *Cervus elaphus*, which ranges from the Forest-bed to the present day) have been found in any of the Post-glacial deposits in this district. Though so common in the river-gravels in the Midland and Southern counties, they are never found except in caves until we get much farther south or east. Leeds, I believe, is the nearest locality where they occur. This would seem to imply that their remains were wiped off the area by the great ice-sheet which occupied what is now the Irish Sea and its tributary river-systems, and only left in the shelter of caves to which it could have no direct access. Brown bear, horse, red deer, reindeer, megaceros, the more modern Bovidæ, and other more recent forms are not uncommon in the Post-glacial beds; but the older cave mammals seem conspicuous only by their absence."

Clapham, Lancaster, Oct. 6 R. H. TIDDEMAN

Carbon Battery Plates

MR. T. W. FLETCHER will obtain what he requires from the India Rubber, Gutta Percha, and Telegraph Works Co., No. 100, Cannon Street, E.C.

I have 12,000 Carbons, or as we call them Graphite Plates, at work at this moment, and for some years past have obtained them solely from the above Company.

Tunbridge, Oct. 14 CHARLES V. WALKER

ASTRONOMICAL ALMANACS *

III.—*Foundation of the Nautical Almanac*

DURING his voyage of 1761 to the island of Saint Helena, for the purpose of observing the transit of Venus, Maskelyne, like La Caille, investigated the methods for determining longitudes at sea, and on his return, in "The British Mariner's Guide" (1763), proposed to adopt the plan of an almanac sketched by the French astronomer. There existed at this time in England a commission instituted by George III. for the discovery of longitudes at sea; † it was a body almost analogous to the present French "Bureau des Longitudes." Maskelyne took many steps to induce this Commission to approve of his proposal; and, at the same time, he commissioned several ship-captains to put it to the test. Their reports confirmed his assertions, and on February 9, 1765, Maskelyne presented to the Commissioner of Longitude a detailed report,‡ in which, besides a complete exposition of the method and plan of a nautical almanac, he gave from the entries in the log-books the result of this new method. The proposition of the wise abbé was adopted, and Maskelyne was entrusted with the calculation and publication of the "Nautical Almanac

* Continued from p. 352.

† "The Commissioners appointed by Act of Parliament for the discovery of longitude at Sea, and for examining, trying, and judging of all Proposals, Experiments and Imperiments (*sic*) relative to the same, and encouraging attempts to find a Northern Passage between the Atlantic and Pacific Oceans, and to approach the Northern Pole."

‡ It is found *in extenso* in the "New and Correct Tables of the Motions of the Sun and Moon," by Tobias Mayer: London, 1770. Published by order of the Commissioner of Longitude.

and Astronomical Ephemeris." The Commissioners did more; they ordered the printing of the Tables of the Moon, left by Tobias Mayer, according to which the lunar distances were to be calculated. At the same time parliament voted a sum of 3,000*l.* to the widow of the astronomer of Göttingen, and a sum of 300*l.* to Euler, for having furnished to Mayer the theorems which he used to construct his theory.*

The first volume of the "Nautical Almanac" is concerned with the year 1767, and appeared in 1766. Although infinitely superior to the "Connaissance des Temps" for 1767, this publication is far from the perfection which it has since attained. Its object is two-fold, but not well-defined; it contains much information useless to the astronomer, and many things besides which the mariner could dispense with. There is first a calendar with the aspects of the planets; then a solar table giving for each day the longitude of the sun at noon, calculated to $\frac{1}{100}$ of a second; the right ascension of the sun in time to $\frac{1}{10}$ of a second, his declination to a second, and the equation of the time; next follow the eclipses of the four first satellites of Jupiter; then tables of the planets, giving the longitude (to a second) and the latitude (to a minute), heliocentric and geocentric, the declination (to a second), the hour of the passage of the meridian (to a minute), every third day for Mercury, and every sixth day for the other planets. The table following gives, for every day from noon to midnight, the longitude (to the $\frac{1}{100}$ of a second) and the latitude (to a second) of the moon, her right ascension and declination from noon to midnight, as well as her apparent semi-diameter and horizontal parallax. Then follow the distances calculated for every three hours, of the moon from the sun and from a certain number of stars of the first magnitude, and lastly the configuration of the satellites of Jupiter for every day in the year, at 5.30 P.M. The work is completed by detailed and well-written instructions, telling the signification and use of the various tables contained in the volume.

The calculations are, moreover, made with an amount of care far greater, according to Lalande, than was ever bestowed on the "Ephémérides." Each article was calculated separately by two persons and verified by a third calculator. In the case of the longitudes, latitudes, right ascension, declination, semi-diameter, and parallax of the moon, these were calculated by one person for noon and another for midnight, and afterwards verified by the mean of the differences which were carried as far as the fourth order.

Some years later, in 1772, three English astronomers, Lyons, Parkinson, and Williams, published some exceedingly convenient tables, entitled, "Tables for correcting the apparent Distance of the Moon and a Star from the Effects of Refraction and Parallax" (Cambridge, 1772), by the aid of which ten minutes sufficed to calculate an observation of distance between the moon and a star, and therefrom to deduce the longitude. The use of the lunar distances became from that time a great convenience. It was in the same year, 1772, that Lalande transferred into the "Connaissance des Temps" for 1774 the calculations of the lunar distances copied in the "Nautical Almanac," "not having," said he, "either the leisure to do it myself, nor the means which the Commission of Longitude of London furnished to the Astronomer-Royal Maskelyne, for maintaining calculators, whose work he had only to superintend and verify." The introduction of these lunar distances doubled the value of the "Connaissance des Temps," which became a work useful at once to astronomers and mariners.

IV. *Foundation of the Berlin "Astronomisches Jahrbuch"*

This same year, 1774, witnessed the appearance of a great number of publications analogous to the *Connaissance des Temps* and the *Nautical Almanac*, all intended to regulate the publication of the Ephemerides, which in nearly all countries astronomers published at different times. Of these we shall mention the "Jahrbuch" of Berlin, the "Ephemerides" of Vienna, and those of Milan.

The idea of the "Berliner Astronomisches Jahrbuch" originated with Lambert. Born August 29, 1728, at Mulhouse, then a free town of Alsace, of parents who kept a small tailor's shop, Lambert received a very incomplete elementary education, which he afterwards supplemented by assiduous labour and persevering determination. In 1748 Count Pierre de Solis entrusted Lambert with the education of his children; this was an opportunity of which he knew how to take advantage. He found in the Chateau of Coire, the abode of this nobleman, an exceedingly rich library, by means of which he not only completed his imperfect education, but from which he drew the elements of one of his finest works, the "Dissertation on the remarkable Properties of Light." Shortly after, in 1763, the restraints to which Protestants were subjected in France, and in particular the law which prohibited them from exercising any public functions, induced him to yield to the invitations of Frederick the Great; Lambert went to live at Berlin, and became, in 1764, a *pensionnaire* of the Royal Academy of Prussia. France thus lost one of her scientific glories; for, not only was Lambert a distinguished astronomer, but pre-eminently remarkable for the universality and extent of his attainments.*

Long before the time to which we refer there had appeared at Berlin Astronomical Ephemerides; the first, due to the astronomer Grischow, date from 1749; it is the "Calendarium ad annum 1749 pro meridianum Berolinense cum approbatione Academicæ regiæ Scientiarum et elegantiarum litterarum Borussiæ." They were carried on by Grischow until 1754, and suffered afterwards many interruptions. It was these Ephemerides which Lambert undertook to revive. According to the plan which he proposed to the Academy of Berlin, each volume of the "Jahrbuch" would appear two years in advance and consist of two parts. One part was devoted to the astronomical ephemerides (Prussia not then having any marine, Lambert had not to trouble himself with nautical ephemerides) and so disposed that it could easily serve for a place of different latitude; the other forming a collection of all the news concerning the astronomical sciences (observations, remarks, and problems). Lambert also proposed to collect, in another work, all the tables serving either for the calculation of the ephemerides or for other astronomical calculations.

The proposal of Lambert having been adopted, an astronomer who was afterwards director of the Berlin observatory, and whose reputation became universal, J. El. Bode, was entrusted, under the direction of Lambert and the nominal superintendence of the Academy, with the numerous calculations which the publication of these Ephemerides necessitated. The first volume appeared in 1774, under the title of "Berliner astonomisches Jahrbuch für 1776, unter aufsicht und mit Genehmhaltung der königlichen Academie der Wischenschaften verfertigt und zum Drucke befördert."

Lambert had the direction of the "Jahrbuch" for only a very short time; death came soon after to deprive Science of one of her most ardent worshippers. Nevertheless his initiative, though of short duration, was successful, and from its first appearance, the work which he founded progressed more notably than those which preceded it.

At the same time also appeared the Ephemerides of Milan,—"Effemeridi artronomiche per l'anno 1775, calculate pol meridiano di Milano, del abbe Angelo de

* Fifty years later, another parliament authorised the printing of the new lunar tables of Hansen, his compatriot, and awarded to that illustrious astronomer a sum of 1,000*l.* by way of national recompense.

* His most important astronomical work is entitled "Insigniores Orbitæ Cometarum Proprietates."

Cesaris." It was also the first volume of a series of ephemerides which have been since continued without interruption.

In 1799 the publication of the Portuguese ephemerides commenced —"Ephemerides astronomicas calculadas para o meridiano Observatorio nacional de universidade de Coimbra, para uso do mesmo Observatorio, e para o da navegaçao Portugueza."

Lastly, in 1756, appeared the ephemerides of Vienna :—"Ephemerides astronomicæ anni 1757, ad meridianum Vindobonensem jussu Augustorum calculis a Maximiliano Hell. Cæsario regio astronomo et Mechanicus experimentalis professore publico et ordinis," which were continued by Triesmecker. The Ephemerides of Vienna were constructed upon the model of the Abbé de la Caille, much more than upon that of the *Connaissance des Temps*. Moreover, at this period, the Ephemerides of La Caille were almost exclusively employed by French astronomers.

(*To be continued.*)

THE BRIGHTON AQUARIUM

IN accordance with an intention entertained previous to resigning the tenure of my office as Curator to the Brighton Aquarium, I propose to give a brief outline of the plan of construction and general system of arrangements obtaining in that institution.

The Brighton Aquarium, while emulated by several buildings of a similar nature, in different parts of the kingdom and on the Continent, still holds its own in being on a scale of magnitude hitherto unsurpassed, more than one of its tanks, in illustration of this, being of sufficient size to accommodate the evolutions of porpoises and other small Cetaceæ. The architect and originator of the undertaking, Mr. Edward Birch, well known as the engineer of the new pier at Hastings, entertained the idea of constructing this Aquarium as long ago as the year 1866 when visiting the one on a small scale then existing at Boulogne; Brighton was selected as a site on account of its proximity to the sea-coast and its great popularity as a place of resort. The works were commenced in the autumn of the year 1869, but owing to various interruptions the building was not formally thrown open to the public until August 1872, the ceremony taking place during the week in which the members of the British Association honoured Brighton as their place of meeting.

The area occupied by the Brighton Aquarium averages 715 feet in length by 100 feet in width, running east and west along the shore line between the sea and the Marine Parade; the principal entrance is at the west end facing the eastern angle of the Royal Albion Hotel. The building internally is divided into two corridors separated from one another by a fernery and considerable interspace. The approach to the first or Western corridor is gained through a spacious entrance-hall supplied with reading-tables, and containing between the pillars which support the roof portable receptacles of sea-water for the display of small marine specimens that would be lost to sight in the larger tanks.

The tanks for ordinary exhibition commence with No. 1 on the left side of the western corridor, and, as shown in the ground-plan, follow in consecutive order round the two corridors, the last, No. 41, immediately facing No. 1. The smallest of these tanks measures 11 feet long by 10 feet broad, and is capable of holding some 4,000 gallons of water, while the largest, No. 6, in the western corridor, and the subject of the accompanying engraving, presents a total frontage, including the two angles of 130 feet, with a greatest width of 30 feet, and contains no less than 110,000 gallons. Every gradation of size occurs between these two extremes, the depth of the water in all ranging from 5 to 6 feet. Supplementary to the foregoing, a series of half-a-dozen shallow octagonal table-tanks occupies a portion of the interspace between the two corridors, these being especially adapted for the exhibition of animals such as starfish, anemones, and others seen to best advantage when viewed perpendicularly through the water. Flanking one side of this same interspace are several ponds fenced off for the reception of seals and other amphibious mammalia and larger Reptilia, while at its further or eastern extremity artistic rock-work runs to a height of 40 feet, thickly planted with choice ferns and suitable exotic plants, and broken in its course by a picturesque waterfall and stream. Tanks 12 to 17 in the eastern corridor, in addition to the stream and basin beneath the waterfall, are set apart for the exclusive exhibition of fresh-water fish, the remaining tanks being devoted to marine species. The bulk of water thus utilised in the fresh and sea-water tanks collectively amounts to 500,000 gallons, and in addition to this several smaller store tanks in the Naturalists' Room, adjoining the eastern corridor, afford accommodation for reserve stock, or for new arrivals before their display to public view.

The style of architecture dominant throughout the building is Italian and highly ornate, the arched roof of the corridors being groined and constructed of variegated bricks, supported on columns of Bath stone, polished serpentine marble, and Aberdeen granite; the capital of each column is elaborately carved in some appropriate marine device, while the floor in correspondence is laid out in acrostic tiles. The divisions constituting the fronts of the tanks are composed each of three sheets of plate glass, each plate having a thickness of one inch, and measuring six feet high by three feet wide, separated from one another and supported centrally by upright massive iron mullions; in the smallest tanks the front is represented by but one of these divisions, while that of the largest, No. 6, consists of as many as eleven. Among other conspicuous structural features of the aquarium demanding notice are the huge masses of rock entering into the composition of the tanks and fernery. Part of these are composed of porous tufa brought from Derbyshire, while the remaining and greater portion presents the appearance at first sight of old Red Sandstone of the Devonian epoch. This latter, however, is entirely artificial, being built up of smaller nondescript fragments, faced with cement and coloured sand, though so true to Nature have the boulders been fashioned and stratigraphically arranged, that more than one eminent geologist has been deceived by their aspect, and it is difficult in looking into the larger tanks to get rid of the impression that some of the miniature picturesque coves characteristic of the Devonshire coast have been transported bodily to Brighton.

The system adopted at the Brighton Aquarium for continually renewing the supply of oxygen necessary for the well-being of the animals agrees with that followed at Berlin, streams of compressed air being constantly forced into the tanks through vulcanite tubes carried to the bottom of the water, and each tank being fitted with a greater or less number of these tubes according to its size. Following the same principle there is no true circulation, each tank being distinctly independent and the same water remaining in it perpetually unless required to be changed on account of turbidity, an accident such as the cracking of a front glass, or for altering the arrangement of the inhabitants. In such cases the tanks are refilled from four large reservoirs situated beneath the corridors, holding in aggregate a quantity approximating but not exceeding that contained in the tanks above, and into which the water is first pumped by a six-horse power centrifugal engine direct from the sea, and thence conveyed by the same force to the tanks, through a main extending round the building.

The system above described, while practical in aquaria at the seaside, where the supply of water is unlimited, does not answer inland, as exemplified in the decadence,

from a scientific point, of the one from which that at Brighton is copied, and even in the former case is associated with serious drawbacks and disadvantages, which forbid it from yielding in compensation for the outlay and labour expended the results realised by those constructed on later and more approved principles. It is impossible, for instance, to keep in health at the Brighton Aquarium the number of fish in comparison to the size of any given tank as will be found in the aquarium at the Crystal Palace or that of Hamburgh, or Copenhagen, or any other constructed on the same principle, though at the same time it is essential to remark, that lately the capabilities of the Brighton tanks have not been turned to their greatest advantage, as instanced in No. 6, holding 110,000 gallons of water, which for many weeks past has been occupied by but three dogfish, a ray, and a few turtle; No. 11, with 9,000 gallons, by two mackerel, and so on. A remaining still greater source of dissatisfaction associated with the non-circulatory system, and yet one capable, perhaps, of full appreciation by those only who have held practical aquarium responsibility, arises from the difficulty, verging upon the impossibility, of maintaining the tanks uniformly bright and clear throughout the building. Some fish foul the water to a much greater extent than others, notably the Flat-fish or Pleuronectidæ, who in a few weeks will render a clear isolated tank too opaque for the opposite side some twenty feet distant to be discerned. The only existing remedy for such a case is to run off the water and supply fresh from the reservoirs beneath; but this water being drawn from the shore-line, the feeding pipe remaining exposed at half tide, is necessarily loaded with impurities, which re-agitated by the action of pumping involves the lapse of several more days before the tank is in a fit state for exhibition. At the suggestion of my predecessor, the late Mr. J. K. Lord, oysters and other bivalve mollusca were introduced into the tanks for the purpose of removing the organic particles which rendered the water turbid, but though these have proved of great service, the root of the evil remains undisturbed, and it is only by the application of the circulatory system, securing with it the more thorough oxygenisation of the water, that the problem is to be effectually solved.

This system, initiated by Mr. W. A. Lloyd at the Hamburgh Aquarium, and now maintained under his personal superintendence at the Crystal Palace, consists in having, in the first place, a bulk of water in the reservoirs beneath exceeding by four or five times the total amount contained in the tanks above, and which, being pumped up by steam power and circulated through the building, takes up in its course by exposure to the atmosphere an amount of oxygen, permitting the preservation in health not only of a much larger number of inhabitants to each tank, but at the same time communicates to the water a degree of clearness and brilliancy unattainable by other means, and which brilliancy is increased or diminished in exact proportion to the uniformity and force of the current so maintained. One theoretical objection urged by the architect of the Brighton Aquarium against the circulatory system, is that in the event of paint or other deleterious substance falling into any one tank the water of the neighbouring tanks would suffer equally. Practically, such mishaps have no business to occur, and though in such a case, on the "siphon" mode of circulation first attempted but abandoned as impractical at Brighton, some mischief might be done, it would be impossible under that to be presently suggested as still feasible at the institution here under consideration, and until the adoption of which the Brighton Aquarium cannot be expected to fully realise the highest anticipations of its promoters, while the greater or less turbidity of its tanks must continue as hitherto a constant source of dissatisfaction to the directors, and of anxiety and mortification to the officers held responsible.

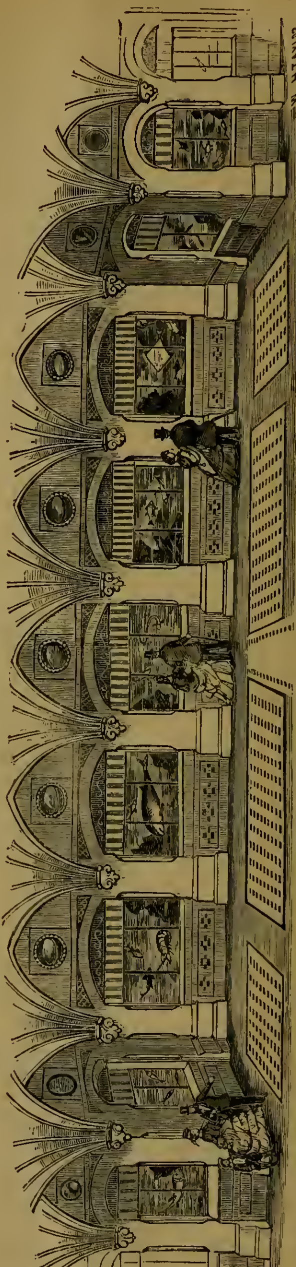

FIG. 1.—Front View of Tank No. 6 (110 ft. long), Western Corridor, Brighton Aquarium.

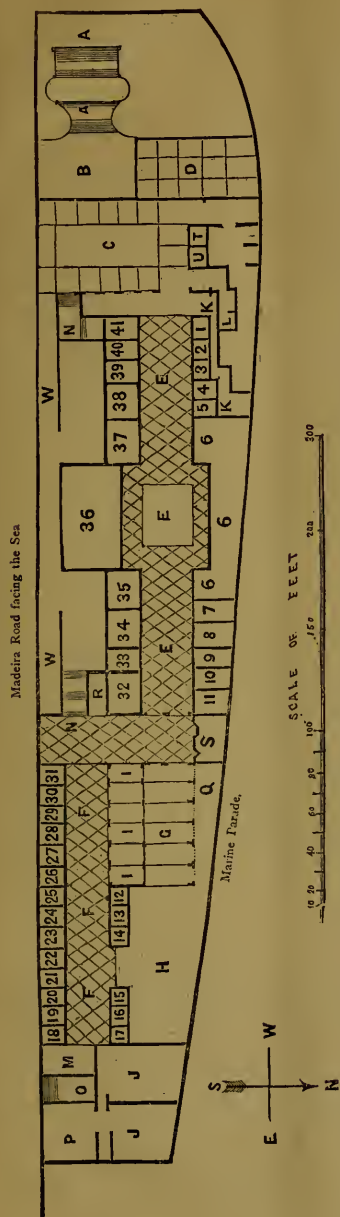

A Steps descending from West End. B Entrance Court. C Entrance Hall and Reading Room. D Restaurant and Dining Hall. EEE Western Corridor with Tanks on each side. FFF Eastern Corridor. G Interspace. H Rockwork, Fernery, and Cascade. III Table Tanks. JJ Engine Room, Stores, &c. KK Ladies' Cloak Room. LL Gentlemen's do. M Naturalist's Rooms. N Steps to Corridors with Promenade over. O Business and Private Entrance. P Curator's Office. Q Rockwork, with Seal-Ponds, &c. R Grotto. S Heating Apparatus. T Clerk's Office. U Board Room. W Inclines for Hand Chairs.

At the eastern extremity of the building there is still a considerable plot of ground unutilised belonging to the company; admirably adapted for the construction of a supplementary reservoir, holding, say, one million and a half gallons, and whose contents, added to those of the existing ones, would yield a body of water sufficient for the purpose. This ground, in fact, being considerably above the level of the tanks, would permit of simplifying matters by pumping the water up from the existing reservoirs to the proposed new one, whence it would circulate through the tanks and return to its original source by the mere force of gravitation. As now the individuality of each tank might be maintained, the water flowing from the main through the existing cocks, and escaping to the reservoirs beneath, through the same overflows, two or more of which are supplied to each tank, which might be enlarged or further multiplied, if requisite to carry off the accelerated stream. Should any tank now become unduly turbid through unforseen circumstances, the accident could be immediately remedied by emptying it into the large reservoirs beneath where so small a quantity in proportion would effect no appreciable alteration, the tank being refilled through the main; while in the event of paint or other poisonous ingredient being upset the water would be run off to waste as under existing circumstances. An important and essential preliminary step to these proposed alterations will, however, be to render the existing reservoirs watertight, their present defective condition in this respect being one of the chief obstacles to the storage of clear water, which in an inland aquarium would have simply proved the ruin of the undertaking. These difficulties surmounted, and the reservoirs filled with water drawn from some little distance off shore, say at the head of the pier close by, and so free from the chalky wash and innumerable organic impurities inseparable from the present supply, the aquarium will be entirely independent of the sea, and much waste of labour now occupied in pumping from it saved. The still more important results accruing to the institution through the uniform clearness of the water, and the capability of each tank to support a number of inhabitants compatible to its size, cannot be overrated.*

Under any circumstances, if the remedy here proposed is not adopted, it is to be trusted that the weak points of the Brighton Aquarium here noticed will prove sufficient to prevent the repetition of the same errors of construction in any of the Aquaria now in contemplation or being built in this country. On the Continent, the type initiated by our own countryman at Hamburgh, and at the Crystal Palace, with such improvements as practical experience dictates, is almost invariably adopted, and it is incumbent that England, as the initiator of the movement, should maintain her lead. So far, from its size and its proximity to the sea, the Brighton Aquarium has been able to achieve results unrealised by any other institution of its description, as instanced in the recent preservation in its tanks of creatures so large as porpoises, and fish so delicately constituted as herrings and mackerel; but these results are by no means commensurate with the expenditure involved in its establishment, and we hope steps will be forthwith taken to remedy the defects indicated.

The Isle of Wight and the Devonshire coast, especially Torquay, are localities offering far greater advantages than Brighton, as zoological stations for the acquisition of specimens, and now that the financial success of large Aquaria under judicious management in centres of sufficient population is well established, the temptation these places offer to an enterprising company cannot be long resisted.

W. SAVILLE KENT

* Defects of construction in the Brighton Aquarium likely to interfere with the future efficiency of the establishment were alluded to without specification, while the building was in the hands of the contractor.—See NATURE, vol. iv. p. 394.

THE RAPIDITY OF DETONATION

A CIRCUMSTANCE of singular interest has recently been revealed in connection with the investigations still being carried on with gun-cotton at Woolwich Arsenal. The experiments made with this powerful explosive have now extended over a period of ten years, and although many discoveries of vital interest have been made by Professor Abel and by Mr. E. O. Brown, who is aiding in the research, the results teach us, before everything, how much more we have yet to learn of the properties of pyroxilin. First of all, the violence of its explosion had to be tamed, then a compressed form of the material was devised, and after that it was shown that, like its sister-explosive, nitro-glycerine, gun-cotton could be violently detonated, if ignited by a charge of fulminate. Gun-cotton, in fact, turns out to be sympathetic, for, according to the energy with which it is inflamed, so it responds in its behaviour: thus, if gently ignited by a spark, the cotton, in the form of yarn, smouldered slowly away; when set fire to by a flame, it burnt up rapidly; if in the form of a charge it was exploded in a mine or a fire-arm, it at once resented the shock and replied with corresponding energy, behaving like gunpowder under similar circumstances; while, lastly, if fired with great violence with a few grains of fulminate, it is detonated with as much force and with the same terrible effect as its instigator.

More recently, as many may have heard, our investigators have succeeded in detonating, or, in other words, exploding to the best advantage, gun-cotton when in a damp condition; and in this state the explosion is every bit as violent as when the material is dry. This grand discovery is naturally of the utmost importance, because, although many objections may be advanced as to the danger of storing and using gun-cotton when dry, the most nervous of us would scarcely hesitate to employ it sopping wet. In this latter condition the material is, strange to say, not only non-explosive, but positively non-inflammable; so much so, indeed, that it would be probably as serviceable in putting out a fire as a wet blanket or a damp towel would be. It can neither be inflamed nor exploded when wet; and further, unless one has the key to its detonation—a little fulminate of mercury—it is of no more value as an explosive than so much wet paper pulp. When placed in contact, however, with a fuse of the proper construction and a cake of dry gun-cotton, to start the action, the wet pyroxiline, as we have said before, detonates as readily as when the moisture amounts to but a fraction of a per cent. Moreover, the quantity of water in the material is really of no importance, for it has been found that for submarine mines, compressed cakes enclosed in a fishing-net and thrown overboard with a dry primer and a fulminate fuse, will explode with just as much energy as when confined in a water-tight steel case.

It is in respect to this detonation, and more particularly to the rapidity of its action, that we desire to speak at the present moment. Recent experiment has shown that the rapidity with which gun-cotton detonates is altogether unprecedented, the swiftness of the action being truly marvellous. Indeed, with the exception of light and electricity, the detonation of gun-cotton travels faster than anything else we are cognizant of. Thus, detonation will run along a line of gun-cotton cakes, placed so as to touch one another, with a rapidity only inferior to that of electricity, setting fire to a charge or conveying a signal, if desired, almost instantaneously. Twenty thousand feet, or nearly three miles per second, is calculated to be its rate of travelling according to Noble's electric chronoscope. In one experiment forty-two feet of the material was fired, and records secured at every six feet; and in this case the results given were most uniform, for the velocity only varied from nineteen to twenty thousand feet per second, the ratio of transit being in no instance less than this.

To form an approximate idea of this extraordinary rapidity, it is necessary to call to mind the rates of travelling of other mediums. Light and electricity we may leave out of the question, as these are immaterial bodies. A bullet usually flies at the rate of 1,300 feet per second, although rifled barrels have been known to project a shot with a velocity of 1,400 feet. Sound is much slower in travelling, for a second of time is required in getting through some 1,100 feet. A quick match of the most delicate construction would probably be longer still in making way, and a train of gunpowder would be left far behind. So it may be safely affirmed, we think, that the detonation of gun-cotton travels more rapidly than any other known medium, with the exception, we repeat, of light and electricity.

It is curious to note that not every detonating or fulminating substance will induce the detonation of gun-cotton. It seems as if a certain number of vibrations require to be set up—a certain key-note to be struck—in order to secure the decomposition of the material. Thus it is found that fulminate of mercury detonates guncotton readily, while again it is also capable of being detonated by itself; so that if a line of compressed cakes is detonated at one end by a charge of fulminate of mercury, the detonation is communicated rapidly from one cake to another, until they are all consumed. Nor does the force diminish at all as it runs along the line, as might perhaps be imagined; if this were the case, the detonation set up at the beginning of a line would only run up to a certain distance, and there come to a full stop, as soon, that is, as the vibrations are insufficient to explode the gun-cotton. This, however, does not happen in actual experiment; and, on reflection, it stands to reason that if the first cake of pyroxilin is capable of firing the second one, the ninety-ninth is just as ready to detonate the hundredth. Thus the detonation can be carried along a line of any length, and the force is as powerful and violent at the end as it was at the beginning.

This property of gun-cotton may obviously be put to valuable use both in industrial and military operations. In any case where it is of importance that a series of blasting or mining charges should be fired simultaneously, their connection together by means of gun-cotton would ensure such a result. True, the same effect could be obtained by means of an arrangement of insulated wires, the charges being detonated simultaneously with the aid of a battery, but such a plan is not always convenient nor practicable. For cutting down palisades, or stout wooden walls, a line of gun-cotton discs exploded in this way would be most efficacious; and a more ready plan of felling timber does not probably exist than that of placing around the stem of a tree a chain or necklace of the explosive in the form of compressed cakes, the detonation of these dividing the trunk as sharply as the keenest axe.

NOTES

WE read in the *Daily News*:—"Mr. Henry Cole, C.B., presided at the annual meeting of the Hanley School of Art, on Monday evening, and after speaking of the results of the South Kensington Museum, said it was his painful duty to announce that this organisation, which had borne such great fruits, and which was so highly prized by the nation, and was so indispensable to the commercial and social progress of this country, was in jeopardy. The Government contemplated changes which were directly opposed to the further development of the Science and Art Department. It had hitherto flourished under a management which ensured individual Parliamentary responsibility, but it was now proposed to hand over South Kensington to the Trustees of the British Museum, who were already fully occupied in their own departments. The management of the British Museum was not such as to make them desirous of seeing

it extended to South Kensington, nor were fifty trustees the proper administrators of public money to the amount of hundreds of thousands a year granted to science and art. He appealed to art students throughout the country not to allow the work of the Prince Consort to be destroyed, and the means of their own instruction to be taken away or muddled with old decaying notions. He urged them to call upon their representatives in Parliament—and an election was not far off—to protect their interests and rights from unprincipled invasion; and he offered his humble services, if he could assist them, to preserve the institution which the Prince Consort founded from the hands of the ignorant spoiler. Mr. Melly, M.P., in proposing a vote of thanks to Mr. Cole, spoke in terms of praise of his efforts to spread art and science, and said it would be far more sensible to transfer the British Museum to South Kensington than to place the latter under the management of the British Museum. It was not by following antiquated notions that the work of education was to be carried on, but by adopting the free-trade principle which Mr. Cole had carried out at South Kensington. He was the Cobden and Bright in the education of art and science. He had been in this matter a true free-trader, and in following the public he had served it. Mr. Cole, in responding, offered 50*l.* towards the establishment of a local museum." Surely it is monstrous that while a Royal Commission is sitting to inquire into these matters the Government should thus attempt to make the Commissioners look ridiculous by taking such a step without waiting for their report. This is another instance of the ignorant action of Government in all matters appertaining to Science.

THE *Challenger* reached the coast of Brazil on September 15 last, after a successful but rather stormy voyage across the Atlantic. She was to have left Bahia on September 25 for the Cape of Good Hope.

MR. SCLATER has received a letter from Dr. A. B. Meyer, announcing his return to Vienna after a most successful expedition to New Guinea. Dr. Meyer landed in Mac Cleur's inlet on the west coast, and crossed the main land to the Bay of Geelvink. He has obtained fresh specimens of nearly all the known Paradise-birds, and of one which he belives to be new to science.

THE examination for Natural Science Scholarships, held in common at the same time and with the same papers for Magdalen, Merton, and Jesus Colleges, Oxford, has terminated in the following elections:—At Magdalen College, to the Demyship, Mr. W. W. Jones, of Clifton College; to the Exhibition, Mr. F. J. Bell, of Christ's Hospital. At Merton College, to the Postmasterships, Mr. W. Carter, of Blackburn Science School, and Mr. F. J. Bell, of Christ's Hospital. At Jesus College, to the Scholarship, Mr. E. W. Poulter. It will be seen that Mr. Bell was elected by two colleges and has decided to accept the election to Magdalen. There were fourteen candidates. The election to the Biological Fellowship at Magdalen College took place on Saturday last, when Mr. C. J. F. Yule, of St. John's College, Cambridge, was announced as the successful candidate. The election to the Physics Fellowship at Merton College will not take place until Oct. 30.

WE regret to have to announce the death of M. Jules Pierre Verreaux, Aide-Naturaliste au Musée d'Histoire Naturelle du Jardin des Plantes. M. Verreaux was a great traveller in early life, and enriched the French National Museum by large collections from the Cape and Australia. On his return to Europe, he was for many years scientific assistant to his brother, the late Edward Verreaux, at the Maison Verreaux in the Place Royale at Paris, so well known to naturalists of all countries. After his brother's death, M. Verreaux accepted the office in the Jardin des Plantes, which he held until his decease. M. Verreaux had a very complete and extensive knowledge of the class of birds, and was the author of numerous ornithological memoirs and papers. His loss will be severely felt by ornithologists who have occasion to consult the rich collection in the Jardin des Plantes, and by many friends and correspondents in this country and elsewhere.

WE have also to record the death of Dr. Otto Wacherer, a German physician, resident at Bahia, who made large collections in various branches of Natural History, and was the author of an excellent memoir on the Ophidians of that district of South America, published in the Zoological Society's "Proceedings."

DR. BESSELS, of the *Polaris* expedition, has given evidence that the death of Captain Hall was solely due to natural causes.

SIR C. B. ADDERLEY, M.P., speaking at the annual meeting of Saltley Reformatory yesterday, expressed his satisfaction at the undoubted diminution of crime in this country. He did not attribute the decrease to any change in our system of secondary punishments but to the gradual spread of education and enlightenment, more especially among the lower classes.

ON November 18 there will be an election at Balliol College, Oxford, to a scholarship on the foundation of Miss Hannah Brackenbury, "for the encouragement of the Study of Natural Science;" worth 80*l.* a year (and tuition free) for four years: open to all such candidates as shall not have exceeded eight terms from Matriculation. At ten o'clock, A.M., papers will be set in the following subjects:—(1) Mechanical Philosophy and Physics; (2) Chemistry; (3) Physiology; but candidates will not be expected to offer themselves in more than two of these. There will also be a practical examination in one or more of the above subjects, if the examiners think it expedient. Candidates are requested to communicate their intention to the Master of Balliol by letter, on or before Monday, November 10, enclosing testimonials from their colleges or schools, and (if members of the University) certificates of their Matriculation; and stating the subjects in which they offer themselves for examination.

WE have received the List of the Candidates who took Honours at the May Examination of Science Schools and Classes in connection with the Science and Art Department. We are sorry that our space does not permit us to publish the list of names, which we are glad to see is very large; it is, moreover, very gratifying to notice that in nearly every department a considerable proportion of the successful Candidates have been "self-taught."

THE following science-teachers, who attended the special course of instruction in magnetism and electricity to science-teachers, in connection with the Science and Art Department, having passed first class, are registered as qualified to earn payments in magnetism and electricity:—T. N. Andrews, G. Armstrong, T. Bayley, J. Bresland, R. Brown, W. Cook, S. Cooke, J. Hamilton, H. Harris, J. Harte, D. Low, S. G. Maunder, A. J. Rider, A. Robinson. J. Sayle, J. Simpson, C. Symons, P. H. Trachy, J. Webb, J. W. Woods. The following for the same reason are registered as qualified to earn payment in acoustics, light, and heat:—J. Alexander, T. J. Baker, S. Barbour, J. Beavis, G. R. Begley, P. Doyle, J. B. Duckett, T. Elliott, T. Isherwood, G. Jeffrey, L. M. Leader, E. Leech, E. Magennis, J. Marsahll, J. Moylan, W. Patterson, E. Reynolds, L. J. Ryan, J. Schofield, G. Severs, W. J. Snowdon, W. Sturgess, C. Symons.

THE name of Dr. Kaup, whose death we noted last week, was inadvertently misspelled "Kemp." Jean Jacques Kaup was Grand-ducal Inspector of the Natural History Museum of Darmstadt.

SIR SAMUEL AND LADY BAKER, it is said, have accepted an

invitation from the Geographical Society of New York to visit that city during the summer months of next year.

THE inaugural lectures in connection with the scheme of education adopted by the University of Cambridge for the town of Nottingham, were delivered on the 9th inst. in the Lecture Hall of the Mechanics' Institution of that town, and were largely attended. Mr. E. B. Birks, M.A., Fellow of Trinity, who has been appointed to conduct classes and to lecture on English Literature, gave his inaugural lecture in the afternoon to a large audience, composed principally of ladies, for whom this subject has been specially selected; and in the evening Mr. V. H. Stanton, M.A., Fellow of Trinity, who had been appointed to teach Political Economy, opened his course. On Friday week Mr. T. O. Harding, B.A., B.Sc., Fellow of Trinity, commenced his instruction in "Force and Motion," the introduction to Physical Science. The Session will continue to next April, and will be divided into two terms. For the second term, which will commence after Christmas, arrangements have been made for the study of Astronomy, Physical Geography, and English Constitutional History. Examinations will be held at the conclusion of each Term in the work done, and University Certificates will be granted to those who succeed in them.

WE learn from the *Bulletin International* of the Paris Observatory, that Lieutenant Parem and Dr. Wykander, while passing the winter of 1872–3 on the coast of Spitzbergen, made a series of spectrum observations on the Aurora, and determined seven different spectral lines, which, according to Wykander, are identical with the spectrum at the bottom of the flame of a candle or petroleum lamp.

MESSRS. ROUTLEDGE & SONS, have in the press, a "New Illustrated Natural History," by the Rev. J. G. Wood, M.A., with 500 Illustrations; and "The Book of African Travel," by W. H. G. Kingston. This work is intended to give records of the journeys of all the celebrated travellers in Africa down to the present time. It will be profusely illustrated.

MESSRS. HODDER and STOUGHTON will shortly publish "Life, Wanderings, and Labours in Eastern Africa," with an account of the first successful ascent of the equatorial snow mountain Kilima Njara, and remarks on the East African slave trade, by the Rev. Chas. New, of the Livingstone Search and Relief Expedition, illustrated.

THE annual migration of the butterfly from east to west across the isthmus of Panama in August and September was, according to the *Star*, proceeding. The butterfly has golden green stripes on a black ground, and is very beautiful. It has been recognised by Mr. O. Salvin, of London and Guatemala, as the *Urania fulgens*.

WE have received the diminutive prospectus of what is likely to be at least an ingenious and curious work; it is entitled "Chemistianity," and will contain "2,000 chemical facts, relating to inorganic chemistry, explained within 5,000 lines of oratorical verse, compiled by permission from the works of leading chemists of the day; together with the views of the author (expressed in verse) as to the advantages of a general knowledge of chemistry." If the book is readable it will certainly be a triumph of ingenuity, if not of genius, on the part of the author, Mr. J. C. Sellars, manufacturing chemist, Birkenhead, who is also publisher.

IN the *Chemical News* for Oct. 17 will be found a long list of subjects for prizes to be awarded in May 1874, by the Société Industrielle de Mulhouse.

THE first three parts are published (price 6*d.* each) of "British Marine Algæ; being a popular account of the Seaweeds of Great Britain, their collection and perservation," by W. H. Grattann. It is intended as a cheap and popular rather than scientific handbook to our marine flora, and will apparently serve a very useful purpose as such. The illustrations, though on a small scale, are sufficient to recognise the more striking forms.

THE last two parts, xi. and xii., of the new edition of Griffith and Henfrey's Micrographic Dictionary, bring down the work as far as Hydra. The botanical articles have been written up to the present state of science by the Rev. M. J. Berkeley.

MR. A. ELLEY FINCH has published the lecture he delivered last March before the Sunday Lecture Society, "On the Pursuit of Truth." We think he has done well in so doing, as he shows clearly and shortly the only principles of evidence upon which permanent and satisfactory belief can be founded, showing the distinction between the evidence which satisfies the theologian, the lawyer, and the man of science. Mr. Finch has added many footnotes and appendices, which, though often irrelevant, are in most cases valuable and interesting, the appendices being mostly abstracts of passages from the works of well-known authors bearing more or less on the subject alluded to in the lecture. We wish the lecture a large circulation among the general public, whom it would tend to enlighten.

THE *Gazette de Vos* publishes some statistics with regard to education in Germany, which appear in *La Nature.* According to the latest official information, the German Empire numbers 380 gymnasiums, pro-gymnasiums, and academies (*lycées*); 156 Latin schools (in Bavaria and Wurtemberg); 270 "realschulen," 12 high schools, technical and polytechnic. Prussia possesses besides, 26 provincial schools of arts and industry; Saxony, 5 commercial schools and 4 schools of arts, industry, and architecture; Saxe-Coburg-Gotha, 3 schools of the kind last mentioned; the City of Hamburg possesses a school of art for boys and another for girls. Bavaria has 33 schools of arts, commerce, and agriculture; Prussia, 26 agricultural schools, with 41 winter schools of rural economy. The rest of the German Empire possesses 56 other schools belonging to one or other of these categories. Prussia numbers 260 superior public schools for girls, and the rest of Germany, 54. 143 seminaries for the training of teachers are in full activity in the German Empire during the present year; primary instruction is given in 60,000 schools. All the German States have schools for deaf-mutes and for the blind; Prussia possesses 35 for the former and 14 for the latter. With regard to schools for the artistic professions, Bavaria occupies the first rank, but Wurtemberg and Prussia have latterly made great progress in this direction.

"THE Pearl of the Antilles; or, An Artist in Cuba," by Walter Goodman, is the title of a volume just published by Messrs. King & Co. Since Mr Goodman calls himself an artist, we should have expected a few illustrations of Cuban scenery in his work, but there are none. The work makes no pretensions to be a contribution to the natural history of Cuba, but in a very entertaining manner the author gives a series of sketches of social life on the lovely island.

THE additions to the Zoological Society's collection during the past week include two Weka Rails (*Ocydromus australis*) from New Zealand, presented by the Acclimatisation Society of Otago; an Alligator (*Alligator mississipiensis*) from New Orleans, presented by Capt. M. Cowper; two Patagonian Conures (*Conurus patagonus*) from Chili, two Solitary Tinamous (*Tinamus solitarius*) from Brazil, received in exchange; a Macaque Monkey (*Macacus cynomolgus*) and a Bonnet Monkey (*M. radiatus*) from India, presented by Mr. G. Veitch, and deposited; a Cape Petrel (*Daption capensis*), purchased, from Manilla, which is the first specimen of this bird obtained by the Society.

ON THE FINAL STATE OF A SYSTEM OF MOLECULES IN MOTION SUBJECT TO FORCES OF ANY KIND

LET perfectly elastic molecules of different kinds be in motion within a vessel with perfectly elastic sides, and let each kind of molecules be acted on by forces which have a potential, the form of which may be different for different kinds of molecules.

Let x, y, z, be the the coordinates of a molecule, M, and ξ, η, ζ the components of its velocity, and let it be required to determine the number of molecules of a given kind which, on an average, have their coordinates between x and $x + dx$, y and $y + dy$, z and $z + dz$, and also their component velocities between ξ and $\xi + d\xi$, η and $\eta + d\eta$ and ζ and $\zeta + d\zeta$. This number must depend on the coordinates and the components of velocities and on the limits of these quantities. We may therefore write it

$$dN = f(x, y, z, \xi, \eta, \zeta)\, dx\, dy\, dz\, d\xi\, d\eta\, d\zeta \qquad (1)$$

We shall begin by investigating the manner in which this quantity depends on the components of velocity, before we proceed to determine in what way it depends on the coordinates.

If we distinguish by suffixes the quantities corresponding to different kinds of molecules, the whole number of molecules of the first and second kind within a given space which have velocities within given limits may be written

$$f_1(\xi_1, \eta_1, \zeta_1)\, d\xi_1, d\eta_1, d\zeta_1 = n_1 \qquad (2)$$

and

$$f_2(\xi_2, \eta_2, \zeta_2)\, d\xi_2\, d\eta_2\, d\zeta_2 = n_2 \qquad (3)$$

The number of pairs which can be formed by taking one molecule of each kind is $n_1\, n_2$.

Let a pair of molecules encounter each other, and after the encounter let their component velocities be ξ_1', η_1', ζ_1' and ξ_2', η_2', ζ_2'. The nature of the encounter is completely defined when we know $\xi_2 - \xi_1$, $\eta_2 - \eta_1$, $\zeta_2 - \zeta_1$ the velocity of the second molecule relative to the first before the encounter, and $x_2 - x_1$, $y_2 - y_1$, $z_2 - z_1$ the position of the centre of the second molecule relative to the first at the instant of the encounter. When these quantities are given, $\xi_2' - \xi_1'$, $\eta_2' - \eta_1'$ and $\zeta_2' - \zeta_1'$, the components of the relative velocity after the encounter, are determinable.

Hence, putting α, β, γ for these relative velocities, and a, b, c for the relative positions, we find for the number of molecules of the first kind having velocities between the limits ξ_1 and $\xi_1 + d\xi$, &c., which encounter molecules of the second kind having velocities between the limits ξ_2 and $\xi_2 + d\xi$, &c., in such a way that the relative velocities lie between α and $\alpha + d\alpha$, &c., and the relative positions between a and $a + da$, &c.

$$f_1(\xi_1, \eta_1, \zeta_1)\, d\xi\, d\eta\, d\zeta . f_2(\xi_2, \eta_2, \zeta_2)\, d\xi\, d\eta\, d\zeta . \phi(abc\,\alpha\beta\gamma)\, da\, db\, dc\, d\alpha\, d\beta\, d\gamma \qquad (4$$

and after the encounter the velocity of M_1 will be between the limits ξ_1' and $\xi_1' + d\xi$, &c., and that of M_2 between the limits ξ_2' and $\xi_2' + d\xi$, &c.

The differences of the limits of velocity are equal for both kinds of molecules, and both before and after the encounter.

When the state of motion of the system is in its permanent condition, as many pairs of molecules change their velocities from V_1, V_2 to V_1', V_2' as from V_1', V_2' to V_1, V_2, and the circumstances of the encounter in the one case are precisely similar to those in the second. Hence, omitting for the sake of brevity the quantities $d\xi$, &c., and ϕ, which are of the same value in the two cases, we find—

$$f_1(\xi_1, \eta_1, \zeta_1)\, f_2(\xi_2, \eta_2, \zeta_2) = f_1(\xi_1', \eta_1', \zeta_1')\, f_2(\xi_2', \eta_2', \zeta_2') \qquad (5)$$

writing—

$$\log f(\xi, \eta, \zeta) = F(M V^2, l, m, n) \qquad (6)$$

where l, m, n are the direction cosines of the velocity, V, of the molecule M.

Taking the logarithm of both sides of equation (5)—

$$F^1(M_1 V_1^2 l_1 m_1 n_1) + F_2(M_2 V_2^2 l_2 m_2 n_2) = F_1(M_1 V_1'^2 l_1' m_1 n_1') + F_2(M_2 V_2'^2 l_2' m_2' n_2') \qquad (7)$$

The only necessary relation between the variables before and after the encounter is—

$$M_1 V_1^2 + M_2 V_2^2 = M_1 V_1'^2 + M_2 V_2'^2 \qquad (8)$$

If the righthand side of the equations (7) and (8) are constant, the lefthand sides will also be constant; and since $l_1\, m_1\, n_1$ are independent of $l_2\, m_2\, n_2$ we must have—

$$F_1 = A\, M_1\, V_1^2 \text{ and } F_2 = A\, M_2\, V_2^2 \qquad (9)$$

where A is a quantity independent of the components of velocity, or—

$$f_1(\xi_1, \eta_1, \zeta_1) = C_1 e^{A M_1 V_2^2} \qquad (10)$$

$$f_2(\xi_2, \eta_2, \zeta_2) = C_2 e^{A M_2 V_2^2} \qquad (11)$$

This result as to the distribution of the velocities of the molecules at a given place is independent of the action of finite forces on the molecules during their encounter, for such forces do not affect the velocities during the infinitely short time of the encounter.

We may therefore write equation (1)

$$dN = C e^{AM(\xi^2 + \eta^2 + \zeta^2)}\, d\xi\, d\eta\, d\zeta\, dx\, dy\, dz \qquad (12)$$

where C is a function of $x\,y\,z$ which may be different for different kinds of molecules, while A is the same for every kind of molecule, though it may, for aught we know as yet, vary from one place to another.

Let us now suppose that the kind of molecules under consideration are acted on by a force whose potential is ψ. The variations of x, y, z arising from the motion of the molecules during a time δt are

$$\delta x = \xi\,\delta t, \quad \delta y = \eta\,\delta t, \quad \delta z = \zeta\,\delta t \qquad (13)$$

and those of ξ, η, ζ in the same time due to the action of the force, are

$$\delta\xi = -\frac{d\psi}{dx}\delta t, \quad \delta\eta = -\frac{d\psi}{dy}\delta t, \quad \delta\zeta = -\frac{d\psi}{dz}\delta t \qquad (14)$$

If we make

$$c = \log C \qquad (15$$

$$\log \frac{dN}{d\xi\, d\eta\, d\zeta\, dx\, dy\, dz} = c + A M(\xi^2 + \eta^2 + \zeta^2) \qquad (16)$$

The variation of this quantity due to the variations δx_1 δy_1 δz_1 $\delta\xi_1$ $\delta\eta_1$ $\delta\zeta_1$ is

$$\left.\begin{aligned} &\left(\xi\frac{dc}{dx} + \eta\frac{dc}{dy} + \zeta\frac{dc}{dz}\right)\delta t \\ &- 2AM\left(\xi\frac{d\psi}{dx} + \eta\frac{d\psi}{dy} + \zeta\frac{d\psi}{dz}\right)\delta t \\ &+ M(\xi^2 + \eta^2 + \rho^2)\left(\xi\frac{dA}{dx} + \eta\frac{dA}{dy} + \zeta\frac{dA}{dz}\right)\delta t \end{aligned}\right\} \qquad (17)$$

Since the number of the molecules does not vary during their motion, this quantity is zero, whatever the values of ξ, η, ζ. Hence we have in virtue of the last term—

$$\frac{dA}{d} = 0 \quad \frac{dA}{dy} = 0 \quad \frac{dA}{dz} = 0 \qquad (18)$$

or A is constant throughout the whole region traversed by the molecules.

Next, comparing the first and second terms, we find

$$c = 2AM(\psi + B) \qquad (19)$$

We thus obtain as the complete form of dN

$$dN_1 = e^{(AM_1(\xi_1^2 + \eta_1^2 + \zeta_1^2 + 2\psi_1 + B_1)}\, dx\, dy\, dr\, d\xi\, d\eta\, d\zeta \qquad (20)$$

when A is an absolute constant, the same for every kind of molecule in the vessel, but B_1 belongs to the first kind only. To determine these constants, we must integrate this quantity with respect to the six variables, and equate the result to the number of molecules of the first kind. We must then, by integrating $dN_1\, \frac{1}{2} M_1(\xi_1^2 + \eta_1^2 + \zeta_1^2 + 2\psi_1)$ determine the whole energy of the system, and equate it to the original energy. We shall thus obtain a sufficient number of equations to determine the constant A, common to all the molecules, and B_1, B_2, &c. those belonging to each kind.

The quantity A is essentially negative. Its value determines that of the mean kinetic energy of all the molecules in a given place, which is $-\frac{3}{2}\frac{1}{A}$, and therefore, according to the kinetic theory, it also determines the temperature of the medium at that place. Hence, since A_1, in the permanent state of the system, is the same for every part of the system, it follows that the temperature is everywhere the same, whatever forces act upon the molecules

The number of molecules of the first kind in the element $dz\,dy\,dr$.

$$\left(-\frac{\pi}{A}\right)^{\frac{3}{2}} e^{AM_1(2\psi_1 + B)}\, dx\, dy\, dz \qquad (21)$$

The effect of the force whose potential is ψ_1 is therefore to cause the molecules of the first kind to accumulate in greater numbers in those parts of the vessel towards which the force acts, and

the distribution of each different kind of molecules in the vessel is determined by the forces which act on them in the same way as if no other molecules were present. This agrees with Dalton's doctrine of the distribution of mixed gases.

J. CLERK-MAXWELL

ORIGINAL RESEARCH AS A MEANS OF EDUCATION*

THE subject of the value of original scientific investigation may be considered from many points of view. Of these, that of the national importance of original research is the one which naturally first engages attention; and it does not take long to convince us that almost every great material advance in modern civilisation is due, not to the occurrence of haphazard or fortuitous circumstances, but to the long-continued and disinterested efforts of some man of science. Nor do I need to quote many examples to show us the immediate dependence of the national well-being and progress upon scientific discoveries thus patiently and quietly made. If it had not been for Black's researches on the latent heat of steam, James Watt's great discovery, which has revolutionised the world, would not have been made. Practical applications cannot be made until the scientific facts or principles upon which those applications rest have been discovered. In our own science I might instance hundreds of cases in which discoveries made in the pure spirit of scientific inquiry have (generally in the hands of others than the original investigators) led to results of the first importance to civilisation. Chloroform was first prepared by Liebig in 1834; but it was Simpson who long afterwards applied it to the relief of suffering humanity. Faraday in 1825 discovered benzole, and from it Zinin prepared a substance called aniline, which for many years remained a chemical curiosity only interesting to the scientific man. In due course, however, a practical sphere of usefulness was to be opened out for this little known substance. Perkin discovered that this rare body was capable of yielding splendid colours. Commercial skill then at once seized upon aniline, and, instead of its being made by the ounce, it is now manufactured by thousands of tons, and the bright and beautiful colours which it yields are known all the world over, and are alike pleasing to the eye of the connoisseur of fashion and of the dusky denizen of the forest primæval. Thus, too, the purely scientific researches of our distinguished fellow-citizen Dr. Schunck, respecting the dyeing principle contained in the well-known madder root, laid the foundations for the subsequent discovery, by Graebe and Lieberman, of the artificial production of this naturally occurring principle, termed alizarine, the manufacture of which is now assuming such gigantic proportions. Again, the discovery of chlorine by Scheele, in 1774, lies at the foundation of the whole of our Lancashire trade, for without bleaching powder the cotton and paper manufactures could not exist on their present extended scale. I might almost indefinitely extend this list of discoveries, which, when first made, were apparently far removed from any useful application, but which all at once become the starting-point of a new branch of industry, and a source of benefit or gratification to mankind.

This subject of the national importance of original research is one which is gradually but surely forcing itself on public attention. A few years ago national elementary education was looked upon as a chimera; now it has become the question of the day. As soon as English people see as clearly as we do the imperious necessity for encouraging, stimulating, and upholding original research as containing the seeds of our future position as a nation, they will not be behindhand in securing the free growth of those seeds. It is therefore the bounden duty of all those whose employment or disposition has led them to feel the truth of this great principle, to leave no stone unturned to make widely known and keenly felt the importance of the national encouragement of original investigation.

It might have been a useful task for me to contrast what is done in other countries for the encouragement of free inquiry and research, and what is done, or rather left undone, in England. We should have seen that on the Continent of Europe, to a great extent, and in the United States, in some measure, those who have to wield the sceptre of government are not only aware of the national importance of original research, but, what is more, that they act up to their convictions, whilst we feel that the same cannot be said in our country. We should have seen that in Germany the facilities given in the universities, which are Government institutions, and in the other numerous and well-organised scientific educational establishments, to original research are very great; that an original investigation in some branch of human knowledge is considered the usual termination of the student's university career; and that degrees are generally given only when some new observations or experiments have been added to the mass of human knowledge. We should find that the position of professor is mainly influenced by the amount and quality of his original researches, and that this power, and not any secondary or subsidiary ones, as is sometimes the case with us, is taken as the proof of a man's fitness to fill the professorial chair.

It is my wish, however engrossing this view of the subject may be, to ask you to consider to-day another aspect of the question—viz. the educational value of original research; the value of personal communication with nature for its own sake, the influence which such employment exerts on the mind, the effect which such studies produce as fitting men for the active duties of life, and the question, therefore, as to how far original investigation should be encouraged as an instrument of intellectual progress. It may be well, however, before we commence this special question, to place clearly before our minds what is meant by scientific inquiry in general, and to see how it is related to the studies and habits of mind with which men up to the dawn of the present, or scientific age, have been familiar.

In the first place, then, the essence of the scientific spirit is that it is free and disinterested. If, therefore, any of the habits of mind, studies, or beliefs in which men have hitherto indulged have not been free nor disinterested, in so far they have not been scientific. In the second place, the spirit of true scientific inquiry knows nothing of tradition or authority. It lays down laws for itself, and refuses to be bound by any others. Scientific education begins with no preconceived idea in accordance with which everything else must be moulded. It starts in simple communion with Nature, and is content to pick up little by little the truth which she is always ready to communicate to patient listeners. Thus step by step and generation by generation, slowly but surely, the perfect edifice of science is being built up, and all those who contribute, however insignificantly, to this great work have the safe assurance that their labour has not been in vain. This process is, it is clear, at once opposed to, and, if successfully carried out, subversive of the old order of things. Between a system based on authority and one founded on freedom of thought and opinion there can never be any united action; and whilst fully acknowledging that intellectual eminence, and, of course, moral excellence, are common to all classes of men, and are not confined to those holding particular opinions, if only they be honest, it is as well that we should admit with equal candour that the followers of the old system have no claim to be called scientific, and that there is, from the nature of things, a great and impassable gulf between us and them.

It does not concern us at present to inquire which of these two systems, the free or the authoritative, is for the future to rule the world. It must now suffice for us to see clearly that the habits of mind necessary for the establishment of the one are absolutely opposed to those needed for the success of the other.

I must, however, here not be misunderstood. It would ill become me, connected as I am with a college to which it has been our constant aim to impart a university character, to undervalue or depreciate the study of subjects other than those included under the head of the physical sciences. Literary studies, whether of modern or ancient authors, giving an acquaintance with the noblest thoughts and opinions of the great men of past ages; historical studies, giving us a knowledge of the acts of men in times gone by; the study of language and philology, as giving a knowledge of how men of all times and countries express their ideas and language; of logic, as pointing out the laws of thought; and above all, that of mathematics, are all matters of the highest importance, the neglect of which would render our education poor and incomplete indeed. The same rules, however, which all acknowledge to be necessary for the teaching of physical science must be applied to the study of all these subjects. In short, the *scientific method* must be employed in all cases and carried out to its fullest extent. Whilst attempts to shackle the mind, or to stifle free inquiry, which have too frequently succeeded in past times, and which may, if we are not on our guard, succeed again, must be repulsed with all our vigour.

* Address by Prof. Roscoe at the opening of the new buildings of the Owens College Manchester.

I would, however, here wish to protest against the supposed materialistic tendency of scientific studies. It is true that certain opinions and professions of belief have been and will be shaken by studying the book of nature; it is also equally true that the study of nature does not and cannot interfere with the highest and noblest aspirations of the mind of man. In the investigations of every branch of science we come at last to a point at which further inquiry becomes impossible, and we are obliged to acknowledge our powerlessness and insignificance. We can see and learn concerning only the minutest fraction of the great whole of nature, and it is with this minute fraction alone that we as men of science are concerned.

In inaugurating, as we are now doing, a scientific department of an institution devoted to the higher education, it may be well to glance for a moment at the preliminary stages through which, in the subject of chemical science, with which alone I am competent to deal, a student must pass to reach the portal of original inquiry. And first let me gratefully acknowledge the help which we have received in endeavouring to find a habitation for a school of chemistry aspiring to be worthy of the intellectual vigour and manufacturing power of the great district of which this city is the centre—help not only of the necessary, and therefore valuable kind of pecuniary assistance generously and willingly given, but help of a personal, and therefore still more valuable kind, without which the funds would have been useless, and our scheme for the foundation of a really great scientific institution would have fallen to the ground. The results of this help you now see in this large theatre, and in the splendidly fitted laboratories behind it. They are, I say it with confidence, the most spacious and best arranged laboratories in Great Britain, and will be found, I believe, second to none in the world for convenience and suitability to their proposed uses. It now remains for my colleagues and myself to discharge our debt; to show that the confidence which has been placed in us has not been misplaced, and to prove year by year that the goods we furnish in the shape of soundly and scientifically educated chemists bring a return worthy of the capital, both in specie and intellect, which has been expended upon their production.

Our mode of instruction in the principles of chemistry is of two distinct kinds: (1), by lectures, accompanied by experimental illustration by the lecturers, as well as by recapitulatory and tutorial classes; and (2), by experimental work practically carried out by the student himself in the laboratory. Both of these means of obtaining command over the facts and principles of our science should be carried on simultaneously; the lectures serve as giving a general view of the main features of the subject; the laboratory work brings the student into direct contact with Nature, and gives him an insight into her processes, which can only thus be obtained. In the lecture room the student forms an idea, as in a panorama, of the general appearance of the country; but it is in the laboratory, as in a walk through a given district, that he first learns what the land he is travelling through is really like. And although we know that we must spend much time and labour if we go on foot, we know that we shall be rewarded by a vivid and lasting impression, and one which may perhaps give a new colour to our lives. It is thus with the study of chemistry; the laboratory is the place where the details of the science are really mastered; and a young man must not expect to become a competent chemist without having passed several years of hard and unremitting toil in solving the sometimes tedious and difficult problems which are presented to him.

It is not necessary for me here to detail to you the particulars of the course of instruction which all students of chemistry, as a rule, go through. Suffice it to say that this course begins at the very A B C of our subject; and, if I am freely to speak my mind, I would say that in general I do not object to take students who know nothing of the science. We first seek to give him some notion of the kind of phenomena with which the science is concerned; we then begin to train him in manipulative dexterity, and, by a graduated series of examples and exercises, make him acquainted with the fixed and exact quantitative laws upon which our science is founded. From the beginning we introduce a strict system of note-taking and of carrying out simple chemical calculations, so as to insure a firm foundation for the subsequent building. The student then begins to learn the properties of the more commonly occurring amongst the sixty-three elementary bodies of which (as far as we are yet aware) the material world is built up, and properties of their compounds. He commences the study of qualitative analysis, and at last he is able to tell you the nature of the exact constituents of any substance, whether of earth, of air, or of sea, of mineral, vegetable, or animal nature, which you may ask him to examine. He has accomplished a great work, and if he has carried his examinations as far as the reactions of the rare elements (as is usually the case with all our students), he is master of the first or qualitative stage of the science. Next the question arises as to the quantity of each constituent present in the given substance, and the second or quantitative stage is reached. This is necessarily a longer and more difficult matter than his preceding task. Not only must the choice of methods of separation and estimation be successful, so as to employ good ones and eschew the bad or inaccurate ones, but skill in manipulation must be forthcoming. All depends on accuracy and care in performing delicate operations, such as weighing, collecting and washing precipitates, and a hundred other manipulations, and the results of many days' work may be in a moment lost by one false step or one careless action.

In all this preliminary work the hand is gradually trained to perform the various mechanical operations, the eye is at the same time taught to observe with care, and the mind to draw the logical inferences from the observed phenomena. Habits of independent thought and ideas of free inquiry are thus at once inculcated; no authority besides that of the senses is appealed to, and no preconceived notions have to be obeyed; the student creates for himself his own material for observation, and draws his own conclusion therefrom. If he is inaccurate either in his manipulation, his observations, or in his conclusion, nature soon finds him out. Something or other is out of order, and he is sent back with the task of finding out his mistake for himself. Not until all this has been accomplished (and very often not then) is the student fit to think about original research. Before he can successfully grapple with new difficulties he must have learned to overcome the old ones. His hand must be dexterous and accustomed to meet all the mechanical difficulties which invariably accompany such investigations; his eye must not only be open to what he expects to see, but, what is far more difficult, it must quickly seize upon the occurrence of phenomena which he does *not* expect to see; his mind, working, perhaps, with a leading thought—for without this, original work is almost impossible—must be free in its power to grasp any new combination of ideas to which the phenomena may suddenly and unexpectually give rise, and be willing at once to relinquish a favourite and cherished hypothesis if the results of experiment prove that hypothesis to be erroneous. This dexterity of hand, quickness and keenness of sight, and pliability of mind must in greater or lesser degree be possessed by all who would undertake original scientific work. I do not mention as a preliminary necessity a competent theoretical knowledge of the phenomena and laws of our science, because, though this is a matter of course, many having this knowledge will altogether fail, owing to their not possessing the other requisites.

In carrying out, then, even the simplest original investigation, some or all of these requirements are needed. In addition, other faculties are called into play by the very fact of the phenomena being in part at least new. Not only do we ourselves not know what to expect, but nobody can tell us what will happen. We are exploring new country, and our outlook must therefore be doubly sharp; we must be prepared for every possible event, and ready to meet every change of fortune. We must, like a traveller, not be discouraged by reverses, but patiently persevere in our course, feeling convinced that the path, which for a long time may be a thorny one, must in due course lead us to a point from which we shall enjoy an extended view of the surrounding country, and be able to trace the tortuous paths by which the elevation was reached. The faculties which are called into active operation in the prosecution of experimental scientific research are, in fact, exactly those which are valuable in the every-day occurrences of life, the proper employment of which leads to success in whatever channel they may happen to be directed. A man who has learnt how successfully to meet the difficulties and overcome the obstacles which occur in every experimental investigation, is able to grapple with difficulties and obstacles of a similar character with which he comes in contact in after-life.

(*To be continued.*)

CONDUCTING POWER FOR HEAT OF CERTAIN ROCKS*

A collection of more than twenty specimens of rocks of the best marked descriptions were chosen for the purpose, and were cut to a uniform shape and size by Messrs. Walker, Emley, and Beall, of Newcastle-on-Tyne, and a part of them were subjected to experiment. The plates are circular, 5 in. in diameter, and half-an-inch thick, and they are as smoothly and accurately ground to this uniform size as was possible in the case of some of the refractory substances as granite, whinstone, &c., that were employed. On the other hand, many more friable and softer rocks, as chalk, coal, marl, &c., are not included in the list of sample sections now collected.

The purpose of the present paper is simply to establish from the experiments the general *bad* conducting powers of the harder rocks, and to corroborate in the case of a few examples that were numerically reduced the conclusions of a similar kind that were obtained by Peclet.

The rock-plate to be tested is placed on a flat-topped tin boiler of its own diameter to raise its temperature on the under-side to the boiling-point of water, while on its upper side a conical flat-bottomed tin flask of spring-cold water is placed, and absorbs the heat transmitted through the rock section from its heated side. A thermometer inserted through a cork in this flask marks the rise of temperature and the quantity of heat transmitted through the rock.

A small quantity of heat is also intercepted and absorbed by it which requires a part of the higher temperature on the heated side to introduce it into the rock, but this quantity is so small compared to the quantity which passes through it and enters the water, that it may easily be allowed for by a suitable correction.

The flask above the rock contained about ½ lb. of water, and under the action of the steam heat below, it rose in temperature about 1° in 35 seconds for *slate*, and 1° F. in 38 or 40 seconds for different kinds of hard and close-grained rocks, as granite, serpentine, marble, and sandstone; while the time occupied for a similar rise in temperature was greatest in the case of a specimen of black shale from the coal-measures round Newcastle, when the thermometer rose 1° in 48 or 50 seconds, or *slower than* in the case of slate in the proportion of about 5 : 8.

In this series of trials it was easily supposed that the real temperature of the surfaces of the rock-plates was considerably different from those of the metallic surfaces in contact with them; and a thermo-electric pair of wires attached to cork-faces was now applied to test the real difference of temperatures of the two faces of the rocks. Two platinum wires were twisted on to the two ends of a piece of iron wire and were connected with the poles of a Thomson's reflective galvanometer. The iron wire itself was bent so as to bring its two twisted ends into contact with the opposite faces of the rock. On testing the thermo-electric arrangement by means of a double tin lid placed between its cork-faces, filled with water of different degrees of temperature on its two sides (which were measured by thermometers inserted in the lids), it was found that a difference of between 3° and 4° F. produced a deflection of 1 division of the galvanometer.

On now taking a plate of marble out of the heating vessel and placing it between the thermopyles, it was found that no sensible heat difference was recorded by it; the rock was reversed, top for bottom between its poles, and the effect was still insensible, although the heat of the finger pressing alone on one of the wire junctions moved the galvanometer 3° or 4°. In order to increase the temperature difference the rock-plate was then brought into contact with the metal surfaces by means of mercury; and the thermometric flask itself being filled with about 10 lbs. of mercury instead of ½ lb. of water, it was found that the thermometer rose 1° in 10 seconds, corresponding to a transmission of 330 heat units per hour through a standard plate 1 in. thick, and 1 square foot in surface. When taken out of its cell and transferred to the galvanometer, the temperature difference was now found to be about 7°; giving the rate of conduction about 47 heat units per hour, instead of between 22 and 28 heat units as assigned by Peclet.

The process of lifting the rock out of its cell having undoubtedly produced a loss of the heat difference before the measurement was made; a new mode was now employed, and the wire junctions were pressed against the rock faces *in situ*, being at the same time protected from the heat of the boiler and thermometer plates facing opposite to them by thick felt wads upon which they were fastened to those plates. In this case a very different variation between the two rock-faces was now found the difference in the case of marble being 50° or thereabouts, while the passage of heat into the water thermometer flask was now about 264 heat units per hour, corresponding to a conducting power of about 5¼ heat units per hour. The same process was applied to two kinds of the black shale already described, and their conducting power was found to be much less than that of the fine-grained marble specimen, being at the rate of only 2 or 2½ heat units per hour. These quantities are not more than ⅛th or ⅒th part of the values obtained by Peclet for the same kinds of rocks. Although time did not permit these experiments to be repeated with a different arrangement of the apparatus, when the sources of error peculiar to each of them would have been easily removed, as their origin in each case is easily explained, yet they confirm provisionally the values of the thermal conductivities found by Peclet; since in two experiments which certainly gave the values alternately in excess and defect, the quantities obtained varied from 5 or 7 to 42 or 47 heat units per hour for a kind of marble to which Peclet assigns 22 or 28 heat units per hour as its conducting power; and in the case of some other rocks of which Peclet describes the conductivity as about half that of the close-grained marble just mentioned, the values found by experiment also indicate a smaller thermal conductivity of these rocks in almost exactly the proportion which Peclet has assigned.

The form in which it will be desirable to repeat these experiments is one which will show the amount and kind of influence exercised by junctions between the surfaces of solid, liquid, and gaseous bodies in retarding the transmission of heat across them; as well as to conclude the actual thermal conductivities of the materials employed, and for this purpose a suitable modification of the apparatus and of the mode of conducting the experiments has been contrived, which it may be expected will fully effect the objects which it is thus intended to obtain.

* Paper read by A. S. Herschel, F.R.A.S., before the British Association, Bradford.

THE DIVERTICULUM OF THE SMALL INTESTINE CONSIDERED AS A RUDIMENTARY STRUCTURE*

THE author took this structure as an illustration in reply to those who are not yet satisfied that structures exist which are useless to the animal body containing them. Referring first to the case of the appendix vermiformis of the great intestine, a survey of the anatomy of the cæcum in various animals, and of the stages of its development in man, leads to the inference that this worm-like appendage is a rudimentary and virtually a useless structure. It has, however, been generally supposed that, being present, it must have some function; and as it was manifest that a thing of this kind at the otherwise closed end of the great intestine is a source of danger by admitting foreign bodies which it could not expel, it has been argued that contrivances designed to avert this danger might be recognised. That it opens at the back instead of at the bottom of the cæcum; that its opening is oblique; that it has a kind of valve; that it is directed more or less upwards; and so on. On the contrary, the worm-like appendix is a vestige, the rudimentary representative of the true cæcum, and all these supposed contrivances by which the danger is lessened are simply the result of the forward and downward development of the great intestine away from the resisting wall of the abdominal cavity against which the appendix and back of the intestine lie. Although from this cause the appendix vermiformis is not nearly so dangerous a structure as it might have been, it is, notwithstanding, occasionally the cause of death. The author knew of several cases of this, and every experienced pathologist must have met with it. Foreign matters get impacted, causing ulceration, and perforation takes place, followed after a few hours by death.

The conclusion, however, that there are parts within the animal body which are useless, and worse than useless because dangerous, is so distasteful to the adherents of the extreme theological school that they will rather fall back on the bare possibility of some unknown function even for such a rudiment. The diverticulum of the small intestine may be employed here to complete the argument. Although in a classification of rudimentary

* Abstract of a paper read by Prof. Struthers, F.R.S.E., of Aberdeen, before the British Association, Bradford.

structures they would be placed in different groups, the one being normal though often varying, the other only occasional, they are on the same footing for the purposes of this argument. It is known to be a vestige of the structure joining the intestine by which, at an early stage of the evolution of the animal frame, nourishment is introduced. All trace of it usually disappears, but occasionally part of it remains as a pouch opening from the small intestine. It has the usual coats of intestine, the inner coat presenting the same food-absorbing villi. It is therefore acting, but no one will argue that it is designed for use in those comparatively few persons who possess it. Unfortunately it is sometimes the cause of death. The author had met with cases of this, and it is well known to surgeons. It may be unable to expel its contents; or by adhering to a neighbouring part a noose is formed, a most dangerous condition, a sort of bowel-trap, through which a knuckle of intestine slips, and strangulation, followed by death, is the result. Here then we have an elaborate structure which is useless, or worse because dangerous. Were a railway contractor to leave open a siding which he had used in the construction of the line, the train might dash into it and a fatal accident result. This is exactly what is done when this diverticulum of the small intestine is left unclosed, and the fatal accident occasionally occurs. Were further illustration necessary we might refer to the fact of disease sometimes attacking that functionless structure the rudimentary breast in the male.

The consideration of such structures as the diverticulum may be said not to take us farther than to clear the ground, showing us that we have been on the wrong path. But a survey of rudimentary structures generally carries us farther. On the hypothesis of the independent origin of species they are unintelligible, while the hypothesis of evolution furnishes a clue to the whole. The facts of embryology, of palæontology, of rudimentary as well as developed structures are harmonised, and the whole present themselves as the result of the operation of a great law, the equivalent in the organic world of the law of gravitation in the inorganic. Although we do not as yet see so well how this biological law operates, the anatomist sees enough to make him feel that he is shut up to some form or other of the theory of evolution, and that the notion which we imbibed in our early years, and have long cherished, that so-called species arose independently of each other, must be a mistake.

The slow progress which this view has made in this country compared with Germany, the author attributed partly to the teleological bias which anatomy early received among us, but mainly to the fact that anatomy has been taught in the medical schools of this country for the most part as a mass of detail in its professional application, without reference to the ideas which it suggests when more widely and profoundly studied as a science.

SCIENTIFIC SERIALS

Ocean Highways, October.—The principal article in this month's number is one by Lieut. Salaverry, of the Peruvian Navy, on the "Navigation of the Upper Amazon and its Peruvian Tributaries," in which he gives some very interesting particulars of the measures that have been adopted by the Peruvian Government to open up and encourage the flow of commerce along the great fluvial highways which connect the rich provinces of the Andes with the Atlantic. The amount of work done by the Peruvian Government during the last few years in the exploration of the region with which the article is concerned is wonderful, and we are sure quite unknown even to many of those who take an interest in geographical discovery. Captain Davis contributes a second article on the *Challenger*, which is followed by one on the Pacific Railways of the South, *i.e.* the Southern United States. Two very interesting narratives are "A Visit to the Kuh-I Khwajah in Sistan," the place mentioned being a remarkable hill to the west of Naseribad, the chief city of Sistan; and "A Visit to Kuloja," by Mr. Ashton Wentworth Dilke, the plain of Kuloja being "a continuation of the Seven Rivers country running up between the Ala Tau and Thian-Shan Mountains."—Mr. E. G. Ravenstein contributes a paper on "Elmina, and the Dutch Gold Coast;" which is followed by an article on the *Polaris*, the usual reviews, proceedings of societies, &c. There are Maps of the former Dutch Possessions on the Gold Coast, of the Amazonas in Peru, of the Pacific Railways of the South, and a Chart of the *Challenger's* course to the Cape de Verde Islands.

Bulletin de la Société Impériale des Naturalistes de Moscou, No. 3, 1872.—In a paper on tantalum, in this number, M. Herman describes five different combinations of the metal with oxygen, two only having been hitherto known.—There are several zoological and botanical lists,—M. Becker gives an account of beetles and flies met with on a journey to the Astrachan region; Mr. M'Lachlan gives drawings of some new species of Phryganides, and a Chrysopa, found in Finland and the Caucasus; M. Hochhuth enumerates the beetles of Kien and Volhynien, &c., while M. Lindemann furnishes a report on the formation of his herbarium.—M. Lubimoff's paper on a new theory of the field of vision and magnification of optical instruments, has been elsewhere noticed in our columns.

No. 4 (1872) commences with an interesting article, with illustrations, by M. Mayewski, on evolution of the barbules of *Begonia manicata*, showing the various stages from that of simple hairs consisting only of epidermic cells.—Some strictures on M. Lubimoff's views as to the field of vision are offered by M. Bredichin, who thinks the theory neither new nor exact.—M. Hochhuth continues his list of beetles (as also in the following number), and M. Kryloff describes some geological formations in the Government of Kostroma.—Dr. Dreschler communicates an account of a collection of mathematical and physical apparatus in Dresden: and the number concludes with a table of meteorological observation in Moscow, in 1872.

SOCIETIES AND ACADEMIES

LONDON

Royal Horticultural Society, Sept. 17.—General Meeting.—Mr. Henry Little in the chair.—The Rev. M. J. Berkeley called attention to some pears, part of which were cracked and small, while the rest were perfect. They had been taken from opposite sides of the same tree, and the difference was probably caused by injury from wind when in a young state.—Mr. Bull exhibited for the first time *Odontoglossum Roezlii*, a near ally of *O. vexillarium*, and which Prof. Reichenbach suggests may be a hybrid between that species and *O. Phalænopsis*.

Oct. 1.—General Meeting.—Mr. Henry Little in the chair.—The Rev. M J. Berkeley alluded to the numerous interesting and rare species of fungi which were exhibited. *Paxillus atrotomentosus*, sent by the Rev. W. W. Newbould from Woburn; *Russula aurata*, by Miss Hubbard, from Horsham; *Hydnum squamosum*, new to Britain, from Somerset, by Mr. Aubrey Clark; *Cortinarius orellanus*, also new to Britain, from Epping Forest, by W. G. Smith, &c. Mr. Berkeley also referred to Schwendener's theory as to the nature of lichens. Bornet had recently published an admirable paper in support of the same views. He himself, however, was not convinced of their correctness. On the contrary he believed he had seen the gonidia of *Parmelia* originating from hyphæ within the cells of some drift wood from the Arctic regions. He also read a letter from Dr. Thwaites, of Ceylon, who thought that the symmetrical growth of the lichens was an argument against one portion being parasitic on the other.

PHILADELPHIA

Academy of Natural Sciences, June 10.—Dr. Ruschenberger, president, in the chair.—Mr. Gentry made the following remarks:—At the last meeting of the Academy, Mr. Meehan made some observations upon the peculiar structure of the flowers of *Pedicularis canadensis*, observing that he had vainly watched them during two seasons with the view of determining the manner in which they were fertilised. He further said that he had noticed that they received the attention of a species of humble-bee, for the sake of their honey, which, in order to accomplish its purpose, always bored a hole into the side of the tube. On Wednesday morning last, I visited a spot where the plants were growing luxuriantly, affording an interesting field for observation. It was not long before I observed a *Bombus terrestris* to alight upon the outer side of the tube of a flower, at a distance of three feet from me. At this distance it did seem as if the bee in order to obtain the honey which it secretes, produced a slit into the tube, as Mr. Meehan observed. But the movements of the bee being so quick, and the distance too great to judge accurately, I ap-

proached the insect by degrees, until I was within three inches of it, when the whole process became apparent. The bee, however, was so intent upon its labours, as not to take any notice of me. The flower is composed of an erect tube, with a natural cleft running along its lateral walls from above, through one-third its entire length, presenting outwardly apparently a mere crease, from the manner in which the compressed margins of the upper lip fit into the rolled-in edges of the lateral lobes of the under lip. The upper lip is compressed, arched, and beaked, presenting an aperture at the apex, through which passes a curved pistil, the lower lip is reflexed, consisting of three lobes, one median and two lateral, assuming a platform arrangement. Enclosed within the upper lip are four stamens, didynamous, with their anthers turning backwards, facing each other vertically. When ripe these anthers split upon the inner side, thus giving a fancied resemblance to an oval snuff-box thrown backwards upon its hinges. Each cell is filled with white pollen grains. Now when the bee alights upon the tube, by means of its trunk, it opens the natural cleft above alluded to, and having thus gained partial entrance, it would defeat its intention did not the length of the flower's tube when contrasted with that of the bee's trunk, necessitate the admission of the entire head also. In this operation the lips of the flower are pressed apart, the margins of the upper lip are separated to receive the head, and the pollen grains, already ripe, by the considerable motion to which they are subjected, become dislodged from their cells, and fall down in a dense shower upon the bee's back and head. Having obtained the coveted sweet, it flies to another flower upon a different stalk, as I observed in a score of cases during two days; but before renewing the preceding operations, stations itself awhile upon the lower lip, its head coming in contact with the stigma of the pistil. Then, by means of the hairs that line the inner side of the tarsus of each interior leg, and the constant rubbing together of the parts comprising its trophi or its instrumenta cibaria the attached pollen grains are sent flying in every direction, sure to adhere to the stigma. Whilst observing the above process, I also noticed that after the lips had been pressed apart, and were permitted to regain their position, the upper lip, being somewhat elastic, sprang back to its place with considerable force, sending through the aperture, through which passes the pistil, a complete cloud of pollen, enveloping the stigma upon every side. This operation can be performed artificially, by taking hold of the under lip with the left thumb and fore-finger, and pulling the upper lip backward, by the right, and then releasing the hold of the latter: the upper lip springs to its place, spirting the pollen through the aperture upon the left hand. From the above it is to be seen, that the plant has two chances of being fertilised—one by its own pollen, and the other by that of another. Although the flower seeds abundantly, yet I am disposed to think that it is mainly through the pollen of another that the seeds become perfect. I incline to this opinion because, in an examination of many pods, I noticed that a few seeds were found in a rudimentary condition, apparently manifesting a tendency to abort, while the majority were in a vigorous condition; the former, doubtless, being the effects of self-fertilisation in part, which, as is well-known, is a degenerating process. I desire also to call attention to an interesting discovery which I was enabled to make recently, whilst engaged in an examination of a double flower of *Ranunculus fascicularis*. In the genus Ranunculus, the corolla of a normal flower is made up of five petals, each of which on the inner side of its basal part is usually provided with a scale. This scale from its position is denominated the *nectariferous scale*. In the specimen under consideration three of these scales had assumed the character of petals, agreeing with the flower's true petals in every particular except size, being but three-fourths the dimension of the latter. It very frequently happens that we find, in examining flowers, parts which we can refer to no organ with which we have become acquainted. They appear to be distinct from any of the whorls which make up a perfect flower, although located among them and attached perhaps to them. All such parts are designated as appendages. Under this category are placed the scales that are characteristic of some species of Crowfoot. Prof. Lindley thinks that these small appendages are barren stamens united to the bases of the petals. This opinion I think is a just one. From the facts here indicated it is reasonable to conclude, that the double flowers of the Ranunculus do not always originate by true staminal metamorphosis, but sometimes by scale transformation; also that nectariferous scales when they exist are barren stamens, which favourable conditions may develop into true petals. Whilst examining several specimens of *Potentilla canadensis* lately, I was struck with the variableness displayed in the number of segments which constituted their outer or calycine whorls. This series in *Potentilla*, as is well known, consists of five sepals, with as many intermediate bractlets. In the specimens to which I refer, I counted from seven to ten bractlets. This numerical variation I am confident results from the splitting, so to speak, of some or all of the primary bractlets, as specimens were observed which exhibited all the transitional forms, from a slight indentation at the apex to partial and complete division.

PARIS

Academy of Sciences, Oct. 13.—M. de Quatrefages, president, in the chair.—The president announced the death of M. Antoine Passy.—The following papers were read:—On crystalline dissociation, by MM. Favre and Valson. This portion of the author's researches deals with the estimation of the work done in saline solutions. Tables of the value of this work were given.—Researches on the ancient fauna of the Island of Rodriguez, by M. Alph. Milne-Edwards.—Verification of Huyghens's law by means of the prismatic method, by M. Abria.—Monograph on the fishes of the family of the *Symbranchidæ*, by M. C. Dareste.—On a mechanical purifier for illuminating gas which will also serve to mix vapour with the gas, by M. D. Colladon.—Researches on the action of the so-called antiseptics on carbuncular virus, by M. C. Davaine. THURSDAY, OCTOBER 30, 1873

OUR NATIONAL MUSEUMS

WE may congratulate ourselves that the Museum question is now being taken up with vigour. Not only must the Royal Commission on Science include it among their inquiries, but the Society of Arts is directing public attention to it.

This is the more opportune, as the intention of the Government to transfer to irresponsible trustees the only museums under the direction of a Minister of State has recently been declared, and needs only to be declared to be condemned on all hands.

We now let the following documents speak for themselves. Next week we shall return to the subject :—

I.

Memorial to the Right Honourable W. E. Gladstone, M.P.

"1. We, the undersigned members of the Council and Members of the Society for the Encouragement of Arts, Manufactures, and Commerce, request the attention of Her Majesty's Government to the remarkable proof of the public desire for instruction and pure enjoyment afforded by the examination of works of Art and Science, which has been shown by the opening of the Bethnal Green Museum.

"2. This Museum, established in one of the poorest and busiest districts in London, where men, women, and children are most laboriously employed, has been frequented during three months by more than 700,000 visitors,* a number which probably exceeds that of the visitors to all the other metropolitan museums and galleries during the same period.

"3. The undersigned submit that this museum could never have come into useful existence, and have been instrumental in conferring great benefits on the people, without the aid of Parliament; and they desire to press this fact upon the consideration of Her Majesty's Government, with the hope that they will submit to Parliament the policy so essentially national of voting increased means to facilitate the establishment of museums, libraries, and galleries of Science and Art in large centres of population, wherever such localities are willing to bear their share in the cost."

Appended to this are the signatures of 250 Peers, Members of Parliament, and other well-known and distinguished men.

II.

CORRESPONDENCE RELATING TO THE ABOVE MEMORIAL.

"*The Secretary of the Society of Arts to the Right Hon. W. E. Gladstone, M.P.*

"July 3, 1873.

"SIR,—A memorial relative to the beneficial action of the Bethnal Green Museum, has been prepared by the Society of Arts for presentation to you.

"It has been signed by one hundred and fifty members of the Council and of the Society, of whom twenty-two are peers, and sixty-three are members of the House of Commons. In addition to the above, thirty-seven peers and sixty-three members of the House of Commons, not members of the Society, have expressed their concurrence in the object of the memorial.

"I am directed to request that you will have the kindness to receive a deputation to present the memorial, and to name a day for doing so, giving, if possible, at least a week's notice."

* "The numbers up to the end of September were upwards of one million and a half of people; to 31st December, 1872, only six months and a half, they amounted to 901,464, whilst the number of the general visitors to the British Museum for the whole year 1872 were only 424,068.—October 1873.

"*Mr. Gurdon to the Secretary of the Society of Arts.*

"July 5, 1873.

"SIR,—Mr. Gladstone desires me to acknowledge the receipt of your letter of the 3rd inst., requesting him to receive a deputation to present the memorial from the Society of Arts, on the subject of the museum at Bethnal Green. I am directed to express Mr. Gladstone's sincere regret that the pressure of his duties, as First Lord of the Treasury, renders it absolutely necessary that he should confine his attention to those matters which fall directly within his province; and he therefore trusts that those on whose behalf you have written will kindly excuse him if he asks them to address themselves to the Privy Council Office."

"*The Secretary of the Society of Arts to Mr. Gurdon.*

"SIR,—I have brought before the Council your letter of the 5th July, in reply to mine of the 3rd July, asking Mr. Gladstone to receive a deputation to present a memorial from this Society on the subject of the Bethnal Green Museum. The Council observe that you express Mr. Gladstone's regret that the pressure of his duties as First Lord of the Treasury renders it absolutely necessary that he should confine his attention to those matters which fall directly under his province, and his trust that those on whose behalf the reception of a deputation was sought will kindly excuse him if he asks them to address themselves to the Privy Council Office.

I am directed, in reply, to point out that the memorial, having relation to a subject of vast importance to the education, general cultivation, and social welfare of the people, did appear to the Council to bring the subject strictly within the consideration of the Prime Minister, rather than of a department of the Government. Moreover, it did appear to the Council that the deep interest which the subject excites is manifested by the unusual character of the signatures, being those of 60 peers and 130 members of the House of Commons attached to the memorial, and justified the Council in asking for the special attention of Mr. Gladstone himself.

"Under these circumstances, the Council submit their conviction that the subject involves considerations of principle and policy worthy the attention of the Prime Minister of this country, and too wide in its political and fiscal considerations to be dealt with effectually by any single department of the Government.

"They, therefore, respectfully decline to adopt Mr. Gladstone's suggestion that they should address themselves to the Privy Council Office."

"*Mr. Gurdon to the Secretary of the Society of Arts.*

"SIR,—I am directed by Mr. Gladstone to acknowledge the receipt of your letter of the 18th inst., and to request that you will be kind enough to acquaint the Council of the Society of Arts that the intention of the reply to your communication of July 3 was to point out that, in regard to a subject of the nature of that which you brought before him (viz. the beneficial action of the Bethnal Green Museum), which falls properly within the province of a department of the State appointed to deal with it, the First Lord of the Treasury could not take the initiative out of the hands of that Department.

"This Mr. Gladstone would be doing were he to receive the proposed deputation; and he would be acting contrary to the rules of administration which are necessary for the conduct of public business.

"If, however, the Society of Arts think fit to favour him with a written communication, Mr. Gladstone will himself correspond with the proper department concerning it."

"*The Secretary of the Society of Arts to the Right Hon. W. E. Gladstone, M.P.*

"SIR,—The Council of the Society of Arts have

directed me to reply to Mr. Gurdon's letter of July 22, in which he states that, 'if the Society of Arts think fit to place before you a written communication, you would yourself correspond with the proper department concerning it.'

"The deputation which desired to have the honour of waiting on you, and explaining in detail the objects of the memorial, would have stated that, in their view, the experiment of the Bethnal Green Museum is suggestive of the following points:—

"1. That a general popular desire exists for such museums, and that it would be good national policy for the Government to encourage the establishment of them.

"2. That like primary elementary schools, it would be impossible that such museums could, without State aid and inspection, become part of a national system, aiding technical instruction and secondary education.

"3. That this question, unfettered by any denominational difficulties, is quite ripe for solution; that the necessary expenditure for aiding museums of science and art would be advantageous from every point of view, even remunerative as respects commerce; and, further, would be auxiliary in promoting morality and social good order.

"4. That such museums are absolutely necessary to the industrial progress of the country, which is behind other countries already in the possession of them.

"5. That the time has come when it is necessary that all public museums and galleries of works of science and art receiving Parliamentary aid, should be brought under an intelligible system of administration, controlled by a responsible Minister of State, so as to render them auxiliary to the development of local museums and galleries.

"The Council submit that these are subjects not only of general policy, but involve some new principles of administration, large financial considerations, the reform of old institutions, &c., which it is the province of the general Government, and not of any single department, to deal with. The Council especially desired that the answer they might receive should come direct from yourself as Prime Minister. They could not bide from themselves the knowledge they possessed of the several departmental difficulties which attended the opening of the Bethnal Green Museum, and that they had been made cognizant, through Parliamentary returns and the revised estimates for 1871-2, of the opposition which the Treasury, as lately administered, had persistently offered to carry into effect the decisions made by Her Majesty's Government in 1866, for conducting the Bethnal Green Museum.

"The Council respectfully request you to have the kindness to bring this memorial before Her Majesty's Government. They hope it will meet with favourable consideration, and lead to decisive action; and they will feel obliged by receiving an answer upon it at as early a period as convenient."

"*Mr. Gurdon to the Secretary of the Society of Arts.*

"SIR—Mr. Gladstone desires me to acknowledge the receipt of your letter of October 6th, the contents of which be will not fail to make known to his colleagues."

III.

Resolutions of the Council of the Society of Arts passed at their last Meeting:—

"1. That the undermentioned persons be invited to serve on a Standing Committee for the purpose of bringing under parliamentary responsibility the National Museums and Galleries, so as to extend their benefits to Local Museums, and to make them bear on public Education. The following are the several objects in view for effecting this purpose:—

"2. All Museums and Galleries supported or subsidised by Parliament to be made conducive to the advancement of Education and Technical Instruction to the fullest extent, and be made to extend their advantages to the promotion of original investigations and works in Science and Art.

"3. To extend the benefits of National Museums and Galleries to Local Museums of Science and Art which may desire to be in connection, and to assist them with loans of objects.

"4. To induce Parliament to grant sufficient funds to enable such objects to be systematically collected, especially in view of making such loans.

"5. For carrying out these objects most efficiently, to cause all National Museums and Galleries to be placed under the authority of a Minister of the Crown, being a member of the Cabinet, with direct responsibility to Parliament; thereby rendering unnecessary, for the purpose of executive administration, all unpaid and irresponsible trustees, except those who are trustees under bequests or deeds, who might continue to have the full powers of their trusts, but should not be charged with the expenditure of Parliamentary votes.

"6. To enter into correspondence with all existing Local Museums and the numerous Schools of Science and Art, including Music, now formed throughout the United Kingdom, and to publish suggestions for the establishment of Local Museums.

"7. Also, to cause the Public Libraries and Museums Act (18 and 19 Vic. c. lxx.) to be enlarged, in order to give local authorities increased powers of acting.

Also the members of the Legislature who signed the Bethnal Green Memorial.

(By order) "P. LE NEVE FOSTER,
Secretary."

SPENCER'S DESCRIPTIVE SOCIOLOGY

Descriptive Sociology; or, Groups of Sociological Facts. Classified and arranged by Herbert Spencer. No. I.—English; compiled and abstracted by James Collier. (London: Williams & Norgate.)

NOT long since, an announcement appeared in NATURE of Mr. Herbert Spencer's plan of publishing, not a complete and finished treatise on Socio-

logy, but a collection of classified materials for the use of students and investigators. The origin of this important work is explained in the following extract from the preface to Part I., which has now appeared.

"In preparation for the *Principles of Sociology*, requiring as bases of induction large accumulations of data, fitly arranged for comparison, I, some five years ago, commenced by proxy the collection and organisation of facts presented by societies of different types, past and present: being fortunate enough to secure the services of gentlemen competent to carry on the process in the way I wished. Though this classified compilation of materials was entered upon solely to facilitate my own work; yet, after having brought the mode of classification to a satisfactory form, and after having had some of the tables filled up, I decided to have the undertaking executed with a view to publication: the facts collected and arranged for easy reference and convenient study of their relations, being so presented, apart from hypotheses, as to aid all students of Social Science in testing such conclusions as they have drawn, and in drawing others."

An objection to this scheme, which struck most who noticed its announcement, was that materials thus arranged would form a patch-work of dead scraps, rather than an organic whole. The specimen which was first circulated, relating to one of the barbaric grades of culture, confirmed this unfavourable expectation. Now, however, that a section of the actual work has been published, it is evident that the scheme can be made to carry an interest of its own, and even to serve an educational purpose. This first section is a methodical summary of the development of England, intellectual and moral, from the beginning of its history in Cæsar's time, to about A.D. 1850. At the first glance, it suggests a question which may disconcert not a few of the lecturers and tutors engaged in training students in history at our Universities. This question is, whether the ethnological record of national life ought any longer to be treated as subordinate to the political record of the succession of rulers and the struggles for supremacy of ruling families, or whether the condition of society at its successive periods is for the future to be considered as the main subject, only marked out chronologically by reigns, battles, and treaties. This question has, it is true, been already raised. It is, in fact, the issue between historical chronicle and the philosophy of history as rival subjects of study. But Mr. Spencer's work brings it more clearly and practically into view than any previous one, as will be seen from the following outline of his scheme. It consists of two parts.

The first part is a series of tables, arranged in thirty to thirty-five columns, each with a heading of some department of social life or history, which again are combined into groups. Thus the group of columns relating to the structure of society takes in political, ecclesiastical, and ceremonial departments, under which again we find separately given the laws of marriage and inheritance, the regulation of tribes and castes, the military and ecclesiastical organisation, and the ceremonies and customs of daily life. Next, the group of columns devoted to the functions of society, regulative and operative, contains particulars of the morals, religion, and knowledge of each age, the state o language, and the details of industry, commerce, habitations, food, clothing, and artistic products. Three special columns at the beginning, middle, and end of this long colonnade, contain the skeleton of ordinary history: namely, the principal dates, names of rulers, and political events. Thus, by glancing across any one of the huge double pages, we see the whole condition of England at any selected period. Thus, in the century after the Norman Conquest, the influence of the invaders is observed in the growth of architecture, painting, music, poetry, the introduction of new food and more luxurious living, the importation of canonical law and of mathematics from the East, and so on through all the manifold elements which made up the life of noble and villain in our land. If the page be turned to the 16th century, the picture of English life is not less distinct. The scholastic philosophy is dying out, men's minds are newly set to work by the classical revival, by voyages into new regions, the growth of mercantile adventure and political speculation; chivalry ceases, archery declines; judicial torture is introduced, the "Italian" crime of poisoning becomes frequent; the ancient belief in witchcraft and pervading demons holds its ground, as do the miracle-plays and local festivals; but a highway act is passed, new roads are being made, the new houses have chimneys, their furniture and fare become more luxurious; the power of the old feudal families is destroyed, the Star-Chamber is new-modelled; church-fasts are still observed under pain of imprisonment, and high offices of state are still in the hands of churchmen, but among the signs of momentous change come the dissolution of monasteries, and the distinct appearance of a sect of Protestants. Thus the tabulated record goes on till it ends near the present day, among such items as Trades'-Unions, Divorce Courts, the Manchester School, County Courts, Free Thought, Railways, Rifled Cannon, Præ-Raphaelitism, Chartism, Papal Aggression, and the crowding events of modern manufacture and science.

It is by following the several columns downwards, that the principle of Evolution, the real key to Mr. Spencer's scheme, is brought out into the broadest light. It seems most strange, however, that he should not have placed in its proper niche the evidence of pre-historic archæology. Mr. Spencer can hardly doubt that the stone implements found in England prove the existence of one, or probably two, stone-age populations before the Kelts, who, under the name of Ancient Britons, begin his series. If he acknowledges this, why should a first link so important in his chain of evolution have been dropped? Otherwise the chain is carefully stretched out so as to display it from end to end. In many matters simple and direct progress is the rule. From the Ancient Briton's bow with its bronze-tipped arrows, to the cross-bow, the matchlock-gun, and thence through successive stages to the rifled breech-loader; from the rude arithmetic before the introduction of the "Arabic" numerals, through the long series of importations and discoveries which led to the infinitesimal calculus in its highest modern development; from the early English astronomy, where there was still a solid firmament studded with stars, and revolving on the poles about the central earth, to the period when the perturbations of planets are calculated on the theory of gravitation, and the constitution of the fixed stars examined by the spectroscope—these are among the multitude

of cases illustrating the development of culture in its straightforward course. Harder problems come before us, where we see some institution arise, flourish, and decline within a limited period, as though resulting from a temporary combination of social forces, or answering only a temporary purpose in civilisation.

To take an instance from Mr. Spencer's Table, English history has seen the judicial duel brought in at the Conquest, flourishing for centuries, declining for centuries more, till its last formal relic was abolished in 1820. Again, in the Old English period, marriage appears as a purely civil contract, on the basis of purchase of the wife; then with Christianity comes in the religious sanction, which by 1076 had become so absolute that secular marriages were prohibited: with a strong turn of the tide of public opinion, the English Marriage Act of 1653 treated marriage as a civil contract, to be solemnised before a justice of the peace; till after a series of actions and re-actions, in our own day the civil and ecclesiastical solemnisation stand on an equal footing before the law. Closely similar has been the course of English society on the larger question of a National Church, which, soon after the introduction of Christianity, claimed an all but absolute conformity throughout the nation, practically maintained the claim for ages, and then was forced back to toleration, which has at last left it with a supremacy little more than nominal. This is not the place to discuss these subjects for themselves, but to show how the table before us, by its mere statement of classified events in chronological order, must force even the unwilling student to recognise processes of evolution in every department of social life. The writer of the present notice once asked an eminent English historian, a scholar to whom the records of mediæval politics are as familiar as our daily newspaper is to us, whether he believed in the existence of what is called the philosophy of history. The historian avowed his profound distrust of, and almost disbelief in, any such philosophy. Now it may seem a simple matter to have tabulated the main phenomena of English social and political history in parallel columns, as Mr. Collier has here done under Mr. Spencer's direction, but his tables are a sufficient answer to all disbelievers in the possibility of a science of history. Where the chronicle of individual lives often perplexes and mystifies the scholar, the generalisation of social principles from the chronicler's materials shows an order of human affairs where cause and effect take their inevitable course, as in Physics or Biology.

It may be objected, however, that summing up complex events in short headings, and arranging these in columns, is a rough and ready method often leading to erroneous inferences, and even liable to gross error. It is evidently in order to guard against this that Mr. Spencer follows the first part of his scheme by a second. Here, under their proper headings, the passages from standard authorities which vouch for the brief statements in the tables are given in full, and with references. This part of the work, much the largest in extent, is thus an elaborate historical commonplace-book, containing some thousands of selected quotations. Mr. Collier is on the whole to be congratulated on the completeness of his reading, and the discrimination with which he has chosen his passages. So much information, encumbered with so little rubbish, has never before been brought to bear on the development of English institutions. There is hardly a living student but will gain something by looking through the compilation which relates to his own special subject, whether this be law or morals, education or theology, the division of labour or the rise of modern scientific ideas. Of course it is very far from perfect. There are some actual blunders; a weak authority is often taken where a strong one was to be had; small matters are often put in, and large ones left out; the want of notes leaves no opportunity of correcting an author's half-true statement. Thus under the heading of Accessory Institutions, there is a good account of the Royal Institution and the Pharmaceutical Society, and a mention of the Russell Institution and the Swedenborg Society, but not a word of the Royal Society. An extract from the Pictorial History of England ascribes the system of Sunday Schools to Mr. Robert Raikes, of the *Gloucester Journal*, about 1780, whereas their real inventor, Jonas Hanway, flourished at an earlier date. Again, under the heading of Religious Ideas and Superstitions, various slips are to be noticed. It was natural enough that, years ago, Brand should, in his Antiquities, have considered the country rite of throwing toast to the apple-trees to secure a fruitful year as being a "relic of the heathen sacrifice to Pomona;" but a modern reader quoting him, should never in Brand's old-fashioned way have dragged in a Roman deity to account for a genuine English superstition. Just below this is the following sentence in brackets, and without an author's name:—"The resistance of tides in the Wash caused by their meeting with the ebb-waters is called the Ægar—one of the gods of the Scandinavian mythology." This statement is misleading, and not the less so for having a real etymology hidden behind it. Our English word *eagre*, signifying the "bore" of an estuary, is Anglo-Saxon *eagor*, the sea, and its use merely asserts the plain fact that the sea runs up the channel. It is true that there is a corresponding old Norse word *ægir*, the sea, and that this in Scandinavian mythology becomes the personal name of *Œgir*, the Sea-god. But it does not follow that our eastern counties' word had ever any such mythological notion attached to it. These happen to be the first weak points which struck the writer in glancing over a page or two in quest of errors. It is needless to continue this critical process on a professed book of extracts; enough has been done to show that the proper use of such a work as the present is not so much to furnish the scholar with complete second-hand ideas, as to indicate how the ideas lie and where they may be obtained first-hand.

Mr. Spencer, out of the evidence amassed by the readers collecting facts under his direction, might have made an admirable treatise of the usual kind on the History of English Civilisation. No doubt, however, for years to come lectures will be delivered and articles written full of suggestive facts in the history of culture, which the initiated will recognise as borrowed from the unwieldy pages of this present atlas-like compilation. In the meantime, we may hope that Mr. Spencer's scheme may be carried out through the whole range of savage and civilised life, and that his tables of development of culture (printed on one side of the paper as if in anticipation of such use), may be set up like maps on the

walls of class-rooms. They are certainly to be compared with maps for the range and precision and correlation of parts with which they show their contents at a glance.

E. B. TYLOR

OUR BOOK SHELF

Aus der Urzeit. Bilder aus der Schöpfungsgeschichte, von Prof. Dr. Karl A. Zittel, in München. Mit 78 Halzschnitten. (München: Rudolph Oldenbourg, 1871-2.)

THIS is one of a series of popular works on Science entitled "Die Naturkräfte," that are being published at intervals by Herr Oldenbourg, of Munich. Prof. Zittel, in his preface to the present work, speaks of the vast influence which popular scientific literature is calculated to have upon the entire development of a people, and therefore insists on the great importance of diffusing, in an intelligible manner, among the people thoroughly correct notions of every science, instead of mincing down scientific truths until they lose all that is characteristic or informing. It is, perhaps, of far more importance that scientific books meant for the people should be as absolutely correct and as far advanced as it is possible to be, than those intended for scientific men themselves. The latter can discover and reject the false or imperfect; the former in their ignorance accept what is written as the truth, and the injury thus done is often serious in its consequences and may take a generation or longer to remedy. Popular scientific works, like school text-books of science, ought to be written only by those who are thoroughly masters of their subjects. The book before us seems to us to be in this respect satisfactory. In a series of chapters, each corresponding mainly with one of the great geological periods, the author endeavours to present a series of pictures of the gradual development of our earth, mainly with reference to the life which it supports. He seems to know his subject well in all its aspects, and presents in an interesting and intelligible way the latest results of geological research, with the conclusions derived therefrom by the most advanced thinkers. The illustrations are very good, and the work as a whole is a good specimen of a popular scientific treatise.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

Remarkable Phenomena

IT may be within the memory of some of your readers that between the 15th and 20th August, 1868, a succession of waves reached Sydney, and were recorded by the self-registering tide-gauge. The average interval between the waves was about 25 minutes, and the greatest oscillation 34 inches, measuring from the crest of one wave to the hollow of the next. It was thought at the time that they were earthquake phenomena.

A similar visitation has just reached us, but it was not so marked in its character. The self-registering tide-gauge shows that the disturbance began during the afternoon of the 15th, and attained its maximum between 1 A.M. and 4 A.M. of the 17th, the greatest oscillation, amounting to 5 inches, occurred between 3.15 A.M. and 3 33 A.M. of the 17th, the average interval of the waves at this time was 25 minutes, but the average of 20 between 8 P.M. and 5.30 A.M. was 28 minutes. The waves cannot be traced beyond the 18th.

On the afternoon of the 16th we had a thunderstorm, during which the barometer was very unsteady, and the barograph sheets show some peculiar curves; strange to say, the average interval of the 5 most conspicuous of the barometer curves or waves between 5.40 P.M. and 7.30 P.M. is 25 minutes; the largest oscillation was 0·045 in. of mercury, equal to about 6 inches of water. Just before daylight on the morning of the 17th several fine meteors were seen to N.E., but the observer who reported them to me did not make notes of particulars. At Newcastle, which is a port 60 miles north of Sydney, I have another self-registering tide-gauge, which recorded a disturbance similar to the Sydney one; it began on the afternoon of the 15th and was greatest between 8 P.M. of 16th and 7 A.M. of 17th; the greatest oscillation, 9 inches, occurred between 12.15 A.M. and 12.30 A.M. of 17th, and the average interval of all the waves from 8 P.M. to 5.3 A.M. of 17th, amongst which are several that only occupied 5 minutes, and look like double oscillations, is 20 minutes.

Struck by the circumstances that both sets of waves, though separated by an interval of 5 years, occurred in August, I determined to examine all the tide-gauge sheets since 1866, when the instrument was set up, and was surprised to find a repetition of it every year, the amounts were too small individually to attract notice, but are nevertheless unmistakable, the periods are as follows:—

1866	August	9th to	10th, and again 15th to 21st.
1867	,,	5th ,,	13th, very marked from 9 A.M to midnight of 12th.
1868	,,	15th ,,	20th, remarkable (see beginning of this letter).
1869	,,	11th ,,	17th.
1870	,,	12th ,,	22nd, marked from 5 P.M. of 17th to 4 P.M. of 18th.
1871	,,	9th ,,	10th and 20th to 21st.
1872	,,	10th ,,	13th.
1873	,,	15th ,,	18th, as recorded in this letter.

It is not easy to believe that earthquake phenomena will recur with such regularity, and we must seek another cause depending it would seem on the earth's annual motion, and to a certain extent affecting air and ocean alike.

It would be premature to express a decided opinion without further investigation, which I have not had time to make yet, but it seems very probable that the August meteor stream through or near which the earth passes about 10th August may be the cause. It will be observed that even in the few observations given above there are indications of a five-year period; for the double disturbance of 1866 is reproduced in 1871, and the great disturbance of 1868 is followed by a similar one in 1873.

Sydney Observatory, Aug. 23 H. C. RUSSELL

Periodicity of Rainfall

I DO not altogether agree with Governor Rawson when he says, in his interesting letter in NATURE, vol. viii. p. 245, that "the experience of Barbados is opposed to the theory broached by Mr. Meldrum and Mr. J. N. Lockyer." On the contrary, I rather think that Mr. Rawson's figures support the theory. He has taken 1846 and 1871 as middle maxima years (in my first paper I also took 1848), whereas 1849 and 1872 are probably more correct. Making this slight alteration, we get, according to Mr. Rawson's statistics:—

	Years	Rain. In.	Sums. In.
Min.	1843	45·31	163·67
	1844	74·45	
	1845	43·91	
Max.	1848	63·77	184·42
	1849	52·77	
	1850	67·88	
Min.	1855	77·31	186·70
	1856	48·49	
	1857	60·90	

	Years.	Rain. In.	Sums. In.
Max.	1859	56·22	
	1860	57·91	... ... 187·95
	1861	73·82	
Min.	1866	59·68	
	1867	69·93	... ... 174·21
	1868	44·60	
Max.	1871	41·46	
	1872	48·39	... ... 154·85
	1873	65·00	

Grouping the results we obtain :—

Rain in Max. Years.	Rain in Min. Years.
184·42	163·67
187·95	186·70
154·85	174·21
527·22	524·58 ; showing an ex-

cess of 2·64 in. on the maximum side.

The quinquennial periods, as far as they admit of comparison, give also an excess in favour of the maxima years.

The heavy falls in 1844 and 1855, and the comparatively small fall in 1872, are apparently opposed to the theory; but it should be borne in mind that rainfall is greatly affected by local causes, and that to reveal the effects of a weaker but more general cause we must, as far as possible, eliminate chance, by comparing the total falls in maxima and minima periods. Tried by this preliminary test, the experience of Barbados can scarcely be said to be opposed to the theory.

My main object, however, is to draw attention to some discordances between Mr. Rawson's figures and those given by Mr. Symons in NATURE (vol. vii. p. 143); for until this disagreement be explained, there will be considerable uncertainty respecting the rainfall of Barbados. The following table will show where the two statements are at variance :—

	Years.	Rain. (Mr. Symons.)		Rain. (Mr. Rawson.)	
Min.	1843	45·3		45·31	
	1844	74·5	163·7	74·45	163·79
	1845	43·9		43·91	
Max.	1847	42·5		48·10	
	1848	62·8	158·3	63·77	164·64
	1849	53·0		52·77	
Min.	1855	73·5		77·31	
	1856	46·4	170·7	48·49	186·70
	1857	50·8		60·90	
Max.	1859	55·1		56·22	
	1860	60·4	186·6	57·91	187·95
	1861	71·1		73·82	

The greatest differences are in 1847, 1855, and 1857, and amount (for these three years alone) to 19·4 in.

It is worthy of remark that both statements show an excess on the side of the maxima years; Mr. Rawson's of 2·2 in., and Mr. Symons's of 10·5 in. But how did such great differences arise.

A remark made by Mr. Rawson may explain the matter. He says "the average of the island for twenty-five years, from 1847 to 1871, is 57·74 inches, based upon the mean of three stations in 1843, and increasing to 141 in 1871." Now it would be useful to know how the mean yearly rainfalls were determined. Is the fall given for 1844 (74·45 inches) a mean of the falls at three stations, and the fall for 1872 (48·39 inches) a mean of the falls at 141 stations? If so, and if the other yearly means were similarly obtained, Mr. Symons may not have taken the same number of stations as Mr. Rawson. Yearly means thus determined would not of course be comparable, for even in a small island the rainfall varies greatly according to locality. The rainfall in maxima and minima sunspot years cannot be fairly compared except by taking the same number of gauges and the same stations; and it is desirable that the falls in the intervening years should be given.

"Assuming that sunspots affect all parts of the globe *equally*, and that periodicity prevails in all *alike*," Mr. Rawson, with the above experience of Barbados before him, is "led to the conclusion that it was 'chance alone' that led to the coincidences noticed by Mr. Symons." Now the theory makes neither of these assumptions. It assumes that there is a sunspot periodicity; that this periodicity implies a secular variation of solar heat and radiation; that, therefore, there is a corresponding periodicity of temperature, wind, and rain on our earth; but that, from various counteracting causes, the observations at some stations will not show a periodicity, while those at a large majority of stations, and a mean of all the observations, will do so. In short, with respect to rain, the theory assumes that the annual fall over the globe is subject to a variation, corresponding with the sunspot variation, but that from disturbing influences, local exceptions must be expected. Granting, therefore, that the rainfall of Barbados is opposed to the theory, I do not think it follows that the favourable experience of the British Isles must be owing to chance alone; for that experience is what theory leads us to expect, and it is much more extensive both as to time and space than the experience of Barbados. If England and Barbados were the whole globe, the theory would be well-nigh proved, as far as observation goes; for, according to Mr. Symons's Table 1, there was not, from 1815 to 1864, a single exception to the rule that more rain falls in the maxima years; and if we take the aggregate falls for England and Barbados from 1843 to 1873, it will be found that there was a large excess on the maximum side.

I have now examined 93 rainfall tables from various parts of the globe. They are all I have as yet been able to procure, and they have been published *in extenso*, so that the evidence they afford may be scrutinised. That evidence is such that if no rain at all had fallen at Barbados in the nine principal maxima years since 1843, and the rainfall in the nine minima years were to be put in the other scale of the balance, there would still be a large surplus in favour of the theory. Up to the present time the more numerous the observations, the stronger the evidence. Still I shall be prepared to abandon the theory whenever a preponderance of undoubted facts may be brought against it. But I see no prospect of this, for the rainfalls of England, Scotland, the Continent of Europe, India, Africa, America, and Australia, as far as they have yet been examined, sustain the theory.

C. MELDRUM

Mauritius, Sept. 15

Dr. Sanderson's Experiments and Archebiosis

DR. SANDERSON has strangely misunderstood the wording of my letter which appeared in NATURE on the 9th inst. Any one may see that I did not challenge him to "deal" with my main proposition "that Bacteria are capable of arising in fluids independently of living reproductive or germinal particles." That position was merely alluded to by me in order to show the relevancy of the question which I asked Dr. Sanderson: and the question itself was—"Whether he still believes that Bacteria are killed by a temperature of 100° C. in fluids; and if not upon what grounds he has changed his opinion?"

Whilst tacitly declining to answer this question, Dr. Sanderson now says, "I hope that Dr. Bastian will allow me to decline to enter on the general question." But it is precisely because Dr. Sanderson has distinctly expressed himself upon the general question both at the late meeting of the British Association and in your columns (NATURE, vol. viii. p. 181), that I feel he may, both from a moral and from a scientific point of view, be called upon to reply to the question above quoted.

The need that Dr. Sanderson should express the grounds of his opinion concerning the death point of Bacteria in heated fluids is further shown by Mr. Ray Lankester's communication in last week's NATURE, in which he says, "Dr. Sanderson does not believe that there is a definite relation between the precise temperature to which the infusion is exposed and the destruction of Bacterian contamination." Now if this is really Dr. Sanderson's present opinion, it may not inappropriately be asked whether it is an opinion based upon definite evidence or whether it is a mere surmise? I say the question is not inappropriate because, as Dr. Sanderson will recollect, I have heard from his own lips, since his return from Bradford, that he has made no definite observations upon the subject, and that he is quite unprepared to question the truth of the experimental evidence which I have recently brought forward (Proceed. of Royal Society, Nos. 143 and 145) showing that Bacteria are killed in fluids which have been raised for five minutes to a temperature of 60° C. (140° F.)*

Dr. Sanderson previously supposed that Bacteria were incapable of appearing and rapidly multiplying in certain fluids

* I should have hesitated about referring to what has passed in conversations between Dr. Sanderson and myself, if he had not set the example both in your columns (NATURE, vol. viii. p. 181) and in a discussion at one of the meetings of the Royal Society.

raised to 100° C. and subsequently protected from contamination. He has been convinced that his supposition on this subject was erroneous. And since this period, whilst I have been careful to undertake fresh researches concerning the death point of Bacteria, he has been content to rest in the stage of mere supposition on this most important point, and is now, as it appears, quite unprepared to question the truth of my assertion that Bacteria are killed at 60° C. It is right that the public should know this, and I only regret that Dr. Sanderson himself cannot be induced to inform them as to the real extent of his knowledge upon this part of the subject.

H. CHARLTON BASTIAN

University College, Oct. 20

Foreign Orders

THE acceptance and refusal of foreign orders by British subjects has hitherto been universally misunderstood. The existence of the Queen's Regulations, which you have reprinted in your columns (vol. viii. p. 481), prohibiting the receipt of these orders without special permission, must, after the discussion which took place in the House of Commons during last session, surprise many of your readers, who will naturally ask why regulations so stringent and so habitually disregarded, have been either kept entirely private in the Foreign Office, or, if published, have never been followed up. As it is, I will venture to say that not one out of some hundreds who have received foreign orders are aware of the prohibition or have any obvious means of becoming aware of it. Announcements of the presentation to British subjects (and it is assumed acceptance of by them) of such orders habitually appear in the most conspicuous type of the most widely circulated papers, but never a hint on the part of the Foreign Office that the recipients are violating Her Majesty's rules, as drawn up by itself and signed by the Secretary of State for Foreign Affairs.

Such being the case, it is somewhat singular that the Foreign Office should issue regulations approved by Her Majesty, forbidding British subjects to accept or to wear foreign orders and their decorations, except in the very rare cases in which Her Majesty's permission is obtainable, and yet take no steps through its agents at foreign courts to instruct the habitual givers that Her Majesty not only disapproves of their action, but requires of her subjects to tell them so in the most ungracious of all ways, namely by refusing to accept their favours, and returning the tokens thereof.

Surely if the prohibition to accept is wise and good (and I am the last person to doubt Her Majesty's wisdom) the obvious course for the Foreign Office to pursue is to inform all foreign Sovereigns of the fact, and instruct British subjects to transmit any orders that they may receive or have received to the Foreign Office to be returned to the sovereign who sent them, if the services of the recipient are not of such a nature as to enable him to obtain permission to accept them.

Into the merits of the prohibition I am not disposed to enter at much length. That foreign orders are comparatively valueless in themselves is generally admitted; and it is well understood that not a few are to be had for the asking by men of real or supposed eminence, and others by solicitation from men of no eminence at all, or of doubtful eminence. It would surprise your readers to know how many of these orders there are in the possession of their countrymen, whose habitual disregard of such honours leads them in most cases to toss them into a drawer and say nothing about it to any one but their wives, who think they would suit their necks better than their husbands' long-tailed coats.

Some few (very few) no doubt have a definite scientific or literary value; but so long as the British public are entirely ignorant of this value, they will be held in no higher estimation than the others, nor do I see any way by which the value of a foreign order could be made known and recognised, or by which the title of the recipient to wear it could be appraised

I believe that it is to the rarity of British orders that any desire to obtain foreign ones is mainly due. Had we more, or none, their value would diminish or expire; as, however, I am not prepared to propose either the restriction or multiplication of British orders, a third alternative might be suggested to the Foreign Office, and that is the command to wear them if accepted; which would result in a display in our *soirées* and assemblies of which men of eminence would be heartily ashamed, and lead to a petition for relief, that would be followed by an abandonment of the practice of giving by the powers that be.

D.C.L.

Mr. Forbes on Mr. Mallet's Theory of Volcanic Eruption.

I DO not intend to depart from my purpose, as stated in my last (NATURE, vol. viii. p. 485), to have done with further controversy. I must, however, beg your permission to correct a statement as to a matter of fact which constitutes the prominent feature of Mr. D. Forbes' letter on the above, and which is published in the last number of NATURE.

Mr. Forbes says, and begs your readers to remember that his remarks [namely, in his original review of my translation of "Palmieri"] were altogether directed to the assertions contained in my introductory sketch, and not *comments upon my theory of volcanic energy*—of which Mr. Forbes now says we, viz., he and your readers, as yet know little or nothing. That is to say, nothing beyond what is given in the abstract in the Proceedings of the Royal Society and in my Introduction to Palmieri.

Mr. Forbes' review (NATURE, vol. vii. p. 259) which called forth this correspondence, was no doubt confined to my translation of, and introduction to, "Palmieri's Vesuvius," &c. But in that same introduction was contained a sketch of my theory of volcanic energy—upon which Mr. Forbes deemed himself warranted to make his sweeping condemnation—that it was not probable that this hypothesis will receive the adhesion of either chemist, mineralogist, or geologist.

If this were not a comment upon my theory of volcanic energy I know not what a comment means.

My complaint has been that it was a comment condemnatory—based on erroneous as well as inapplicable premises—and made at a time when, as Mr. Forbes himself in his last admits, he knew very little about that theory, as fully expounded in my paper in the Phil. Trans.

ROBERT MALLET

Oct. 28

Settle-Cave Report

I HAVE just read with considerable astonishment Mr. Tiddeman's letter (NATURE, October 23) relating to an abstract which I never saw till to-day, and for which, therefore, I am not responsible. The whole question of the antiquity of cave-deposits as well as that of those in the Victoria Cave, in particular is treated in my work on "Cave-Hunting," shortly to be published, and therefore I see no reason for entering into any argument based on the distribution of the Pleistocene Mammalia, or to depart from my rule of not entering into a controversial correspondence.

W. BOYD DAWKINS

Owens College, Manchester, Oct. 24

The Oxford Science Fellowships

I WRITE to confirm Prof. Clifton's letter (in the last number of NATURE) respecting Mr. Perry and Oxford Science Fellowships. Nothing, it seems to me, can be more conclusive than the way in which Mr. Perry's letter has been answered. Any remark further of mine on this point would be superfluous.

I will only say that, in the practical part of the examination, no subject could have been chosen better fitted for giving perfectly fair play to all concerned. If it were possible to imagine that any advantage was given, it was, by the choice of the subject, given to those who were unacquainted with the University laboratory.

In conclusion—far from being looked on as an unwelcome intruder, I met with from all, whether candidates or examiners, the most generous courtesy and kindness.

Cambridge, Oct. 24 THE CAMBRIDGE B.A.

PROFESSOR CLIFTON cannot have considered what a great mistake I have been the victim of, or he would not in his hastily written attempt to defend the general science arrangements at Oxford, have forced me to the following explanation. He knows that I stated my case fairly, and he might surely have given credit for this whilst letting us have the benefit of his later information.

1. I have not at hand a copy of my letter to the Warden. I am quite sure that I told him I was a graduate of the Queen's University in Ireland. The Warden simply directed me to the short notice in the *Times* (afterwards given in your columns), said that the election would not be limited to graduates of Oxford, and would altogether depend on the results of the examination held at Merton on Oct. 7. I thought this letter perfectly satisfactory

as to my eligibility, as did several Oxford graduates to whom it was shown. I shall presently refer to Prof. Clifton's "warning."

The examination was to begin on Oct. 7, at 9 A.M. On presenting myself, a gentleman whose name I do not know, told me that the Physics papers would not be given out before Oct. 10, that if I felt inclined to work the paper given to candidates for the *Mathematical* Fellowship I might do so, and credit would be given for Mathematics in the event of two men being equal in the Physics examination. I shall not comment on this promising arrangement, or on the fact that the candidates for the Physics fellowship had not till then heard of the Mathematical paper. Our informant told me that there were grave doubts as to the eligibility of outsiders. He certainly gave me to understand that these doubts extended to *all* who were not Oxford graduates. I understood that some Cambridge men had presented themselves also; that the question of our eligibility was about to be settled with the Registrar of the University, and that if I called on the Warden between four and five in the afternoon (the time mentioned in the original notice) he would be provided with the results of the deliberations.

At 4.30 I found the Warden about to go away somewhere. I had an audience of about two minutes; was asked what College I belonged to (meaning in Oxford).—Not an Oxford man, I answered.—Then he was afraid I was ineligible. I then informed him that I was the graduate of the Queen's University, to whom he had written in June. I suppose he had very little time for apologies, but he let me know, before leaving, that he had misinterpreted the results of some late commission when he wrote in June, and that I need have no hope.

I have stated the grounds for my former general statement. If Prof. Clifton is certain that graduates of Dublin and Cambridge are eligible, we must rely on his information being most correct, but I am troubled to know who is answerable for my being left in ignorance until now, and if anybody knows whether elections are never made of men who would really be ineligible by the laws of the University.

2. He insinuates a deception on my part, in not mentioning his "warning." I take it that Prof. Clifton has partly forgotten the matter of which he speaks. I wrote to him for leave to inspect the Physical Laboratory at Oxford, not certain that he was one of the examiners, but aware that he had charge of that institution and that the examination *must* be held there (see 3). I did not speak of my eligibility.

There is no doubt about the fact that great difficulties are thrown in the way of outsiders, but I should have been wrong if I had laid any blame on Prof. Clifton for taking the only course open to him. The case is simply this: according to the present Physics arrangements at Oxford, outsiders preparing for the October Fellowship examination at Merton could not without giving the greatest imaginable trouble to Prof. Clifton get any opportunity of inspecting the apparatus.

After stating that he was unable to afford me the desired opportunity, he asked if I had ascertained about my eligibility, informing me that the warden or sub-warden was the proper person to apply to. I immediately wrote *that I had already made such an inquiry*, stating the result.

I now infer that he, after receiving my letter and aware that I had made the proper inquiries, allowed both the Warden and myself to remain in ignorance of the grievous mistake. On receiving no answer I felt perfectly certain that the information received from the Warden was correct.

When I last wrote to NATURE I felt grateful to Prof. Clifton for his inquiry, incomplete and worse than useless "warning" as it had been. Surely no one will think that I had any right to introduce his name.

3. He says it was by no means certain that the Practical Physics examination would be held in the Physical Laboratory. Will he assert that in any one of the nineteen colleges of which he speaks, or in the nineteen collectively there is apparatus for conducting such an examination?

He wonders why it should be necessary to inspect the particular apparatus to be employed in the examination. I do not know if Prof. Clifton was really one of the examiners for the fellowship, but surely he cannot have thought about the matter without being aware of the immense importance of a previous acquaintance with the apparatus such as Oxford men are sure to have. I heard by accident in July that there was no delicate apparatus, nor were proper arrangements made for exact experiments in Static Electricity. Can Prof. Clifton not understand that to an outsider such information might be of the greatest importance.

"What arrangement of telescope stand is there for measuring wave-lengths?" "Is there a Soleil's instrument for measuring the angle between the axes in biaxial crystals?" "Will the arrangements for observing deflections of a needle enable us to employ the logarithmic decrement?" These questions and a hundred others as important were constantly distracting me during the four months of preparation.

My letter to Prof. Clifton was, I believe, modest, and showed my respect for him as a man who had done a great work in his attempt to create a Physics School at Oxford. My request was not "unreasonable." I did not know that his presence was necessary during an inspection of the Physical Cabinet of the University. I maintain too, that he has no right to assert that I must feel very uncertain about my own practical knowledge.

London, Oct. 28 JOHN PERRY

Simple Diffraction Experiment

THE apparatus for this experiment consists of a slit and a grating. A slit may be made by ruling a line on a piece of smoked glass. The grating is made by slightly greasing the thumb and forefinger (there is naturally sufficient on the hot and moist hand), and by drawing a piece of clean glass through them so as to obtain alternate parallel light spaces and greasy lines on both sides of the glass; out of several trials a grating may be made which when used in the following manner will give very pretty results.

The grating being placed close to the eye, the slit (with its direction parallel to that of the lines on the grating) is held up before some bright light, as of a candle, and looked at, as if the grating did not exist. Very beautiful and numerous spectra may then be seen ranged on each side of the slit.

The vitreous surface of window glass does not seem to give such good gratings as a worked and polished surface, as for instance that of a weak spectacle lens.

Oxford H. L.

Publication of Learned Societies' Transactions

IN NATURE, vol. viii p. 506 Mr. Röhrs wishes that our learned societies would publish their papers separately. I have urged this before in NATURE, but unsuccessfully. With Transactions such as those of the Royal Society, the present system is almost an absurdity, for papers on most incongruous subjects are bound up together, and the cost is too great. When once a paper is printed, the Council seem to think that there is nothing more to be done, and do not in any way try to make the work known. All papers should be sold separately as cheaply as possible, and on publication, should be advertised in the scientific journals.

If this were done, we should not have men like Prof. Sylvester writing as follows:—"I owe my thanks to M. Radau and the editor of the Annals of the Ecole Normale Superieure for having been at the pains to disentomb the little known conclusions contained therein from their honourable place of sepulture in the Philosophical Transactions." W. B. GIBBS

EXAMINATIONS OF THE SCIENCE AND ART DEPARTMENT IN BIOLOGY

THE syllabus of the Biological subjects in which examinations are held by the Science and Art Department, has undergone considerable modifications in the edition of the Directory which has been recently issued. Animal Physiology, Elementary Botany (including Flowering Plants only), are subjects which at present appear to be best adapted for the purposes of school instruction. They stand, therefore, in no necessarily logical relation to the other two which are grouped together under the head of General Biology. These involve the use of the compound microscope, and some amount of microscopic manipulation. They are therefore better fitted for rather more advanced, or at any rate, older students than the first stages of the subjects first mentioned.

The two subjects included under General Biology have a common first or Elementary stage. After passing this, the candidate may proceed at choice, either with the zoological or the botanical side.

The following extract from the syllabus will show how this arrangement is intended to work, and will afford the best idea of the direction which the examination is likely to give to elementary biological study. It does all that a written examination can do to encourage practical work, and discourage the prevalent habit of cramming from text-books :—

SUBJECTS XVI. AND XVII.—GENERAL BIOLOGY

First Stage or Elementary Course

Questions will be confined to the following subjects with which the candidate will be expected to show practical acquaintance.

1. The form and size ; the results of optical, chemical, and mechanical analysis ; the mode of growth and multiplication ; the conditions of life ; and the results, direct and collateral, of the living activity of *Torula*, *Protococcus*, *Amœba*, *Bacterium*, and of the colourless corpuscles of the blood of man

2. The structure and mode of growth of *Penicilium* ; its mode of multiplication ; the development of *hyphæ* and *mycelium* from *conidia* : the conditions and results of the living activity of this mould.

3. The structure and mode of growth of *Chara* ; the differentiation of axis and appendages, of nodes and internodes ; the structure and arrangement of the nucleated cells of which the body of this plant is composed. The process of cell-division and its laws ; protoplasmic movements ; Chlorophyll ; asexual propagation ; sexual propagation. Development of the pro-embryo and of the embryo.

4. The structure and mode of growth of a Fern. The differentiation of cells into tissues. Epidermis, parenchyma, fibres, ducts, spiral vessels. The Frond as a respiratory and alimentary organ ; air-passages ; stomata. Asexual multiplication. Sporangia and spores. Development of spores ; structure of the Prothallium. Structure and functions of Archegonia, Antheridia and Antherozoids. Development of the embryo.

5. The anatomy and physiology of a flowering-plant, with especial reference to the morphology of the stem and root. Leaves and their modifications. The structure of pollen and ovule. The process of impregnation and the development of the embryo. The resemblances and differences between flowering-plants and ferns.

6. The anatomy and physiology of the frog. The general disposition of the parts of the body, and the plan of structure characteristic of the frog as a vertebrated animal. The structural characters of the tissues of which the body is composed and their ultimate resolution into nucleated cells.

The physiological properties of the tissues.

The form and structure of the chief organs and the modes in which their functions are performed.

The development of the embryo and the metamorphoses of the larva.

7. The anatomy and physiology of the freshwater Polype.
8. The anatomy and physiology of the Lobster or Cray-fish.
9. The anatomy and physiology of the fresh-water Mussel.
10. The anatomy and physiology of the Sea-anemone.

Second Stage or Advanced Course of Subject XVI.

(Division of Animal Morphology and Physiology.)

Questions may be set in all the topics enumerated under the first head, and in addition on :—

The leading facts relating to the anatomy and physiology of the skeleton, of the brain, and of the cerebral nerves ; of the organs of the higher senses ; of the alimentary, circulatory, respiratory, renal, and reproductive apparatus, in the Lamprey, in an osseous fish (Pike or Cod), bird (Pigeon, Fowl, or Duck), in a quadrupedal mammal (Sheep, Rabbit, Dog, or Cat,) and in Man.

2. The morphology of the vertebrate skull and limbs, as exemplified by the *Vertebrata* already mentioned, and by the Dogfish, Horse, Bat, and Porpoise.

3. The general outlines and process of the development of the chick within the egg.

4. The characters of the orders of the *Vertebrata*.

5. The broad facts relating to the geographical and geological distribution of the *Vertebrata*.

6. The anatomy and physiology of insects, as illustrated by Blackbeetle, a Bee, a Butterfly, and an Aphis.

7. The anatomy and physiology of an Earthworm and of a Leech.

8. The anatomy and physiology of a Fluke and of a Tapeworm, and the history of their development.

9. The anatomy and physiology of the *Rotifera* and of the *Polyzoa*.

10. The anatomy and physiology of a Sea-urchin (*Echinus*) and the history of its development.

11. The anatomy and physiology of a Snail and of a Whelk, and of a Cuttlefish, Squid, or *Octopus*.

12. The morphology of the *Hydrozoa*.

13. The anatomy and physiology of the *Infusoria*.

14. The anatomy and physiology of sponges, *Foraminifera* and *Radiolaria*.

Honours.

In this examination questions will be set at the discretion o the Examiner, who will have regard to the state of Zoologica teaching in the country and the means of acquiring information.

Second Stage of Advanced Course of Subject XVII.

(Division of Vegetable Morphology and Physiology.

Questions may be set in all the topics enumerated under the first head, and, in addition, on—

1. The principal modifications in the minute anatomy of the axis in flowering plants.

2. The nature of the parts used for support in climbing plants.

3. The various modes of agamogenesis in flowering plants.

4. The leading facts in the development of the parts of a flower, including that of the pollen, ovule embryo sac, endosperm (albumen), and embryo.

5. The morphology and relations to one another of the parts of the flower and fruit throughout the classes Dicotyledons and Monocotyledons, more especially as exemplified in the following genera :—

Ranunculus, Nymphæa, Capsella, Viola, Stellaria, Malva, Geranium, Ilex.
Eunonymus, Vicia, Rosa, Saxifraga, Lythrum, Epilobium, Anthriscus.
Lonicera, Senecio, Campanula, Erica, Solanum, Plantago, Lamium.
Polygonum, Urtica, Viscum, Fagus.
Orchis, Iris, Potamogeton, Allium, Arum, Lemna, Typha.
Carex, Triticum.

6. The various adaptations by which cross-fertilisation is effected in Flowering plants.

7. The modes by which seeds are diffused.

8. The broad facts of the geographical distribution of Flowering plants.

9. The distinctive characters and origin of the Arctic-alpine flora, and the floras of oceanic islands.

10. The morphology and physiology of the vegetative and reproductive organs in Pinus, Taxus, and Juniperus.

11. The geographical and geological distribution of the genera of Gymnosperms.

12. The morphology and physiology of the vascular cryptogams, more especially with reference to the following types :—

Selaginella, Pilularia, Lycopodium, Equisetum, Polypodium, Lastrea, Osmunda.

13. The morphology and minute anatomy of the Carboniferous Lycopodiaceæ.

14. The morphology and physiology of Mosses and Liverworts as exemplified by Polytrichum (or Funaria) and Marchantia.

15. The morphology and physiology of Algæ as exemplified by—

Fucus, Ceramium, Saprolegnia, Spirogyra, Closterium, Ulva, Volvox, Protococcus, Palmella.

16. The modes of reproduction in Fungi as illustrated by—

Agaricus, Peziza, Penicillium, Peronospora, Mucor, Uredo, Saccharomyces (yeast).

17. The processes of plant nutrition, comparing also their modifications in Fungi, Neottia, and different parasitical plants.

18. The ash constituents of plants and their distribution in th tissues.

19. The influence of heat and light upon plants.

Honours

Questions at the discretion of the examiner, who will have regard to the state of botanical learning in the country, and the means of acquiring information.

ON THE SCIENCE OF WEIGHING AND MEASURING, AND THE STANDARDS OF WEIGHT AND MEASURE *

VII.

Weighing and Measuring Instruments, and their Use

THE instrument universally used for weighing is the balance, with its various modifications. It serves to determine the weight of bodies by comparison with a body of known weight, such as a standard weight. The simplest form of balance is a beam made to vibrate upon a centre or axis of motion, with pans hanging from the extremities of the two arms of the balance. These two pans hold the bodies compared, and their equality or difference of weight can thus be determined.

Balances are of two kinds:—1. Ordinary balances with equal arms, which have the beam suspended by the middle. If an equal-armed balance is accurately adjusted, so that the beam is exactly horizontal when the pans are empty, the beam will also be horizontal, and the balance will be in equilibrium when equal weights are placed in the pans. 2. Balances with unequal arms, in which the beam vibrates upon the centre of motion placed more or less near one of the extremities. In both of these kinds of balance the beams are levers of the first order, the fulcrum upon which the beam vibrates being placed between the power and the weight, that is to say, between the extremities of the beam which support the bodies compared. On the principle of the lever, the power of any weight to move a balance is proportionately greater according as the part of the beam which supports that weight is more distant from the fulcrum or centre of motion of the balance. Hence it follows that the power of the weight to move a balance is in a ratio compounded of the weight itself and of its distance from the centre of motion of the balance. A multiplying or proportionate balance may consequently be constructed for determining the weight of a body placed in the pan suspended from the shorter arm of the bearer, and required to be equal to any multiple of a given unit weight placed in the pan suspended from the longer arm of the beam, termed the weight pan. For this purpose, if the beam be divided into, say three equal parts, and the centre of motion be placed at the first division, one pound placed in the weight pan will form an equipoise with two pounds placed in the other pan, and so on. This principle is greatly extended in larger weighing machines by lengthening the longer arm, through the use of compound levers, so that one pound can be made to form an equipoise with 100 pounds or more.

The ancient Roman balance is perhaps the earliest form of a well-constructed multiplying balance, and corresponds with our modern steelyard. It has been remarked by Sir Gardiner Wilkinson that no instance has been found of the existence of the steelyard before the Roman era. But the principle of its construction was in use amongst the ancient Egyptians, who ascertained the weight of articles suspended from different parts of a scale beam by means of a heavy determinate weight placed in one scale. The Roman balance consists of a determinate weight attached to the longer arm of the beam, and made to traverse along a number of divisions marked upon it. The multiplied power of the traversing weight when resting on the several sub-divisions, as they increase in distance from the centre of motion, is indicated by corresponding figures upon the graduated beam.

The following figure (taken by permission from the "Imperial Journal of Art," vol. i. p. 85) represents an ancient Roman balance of an elegant form, found at Pompeii, and in use A.D. 77. It is described as having the graduated divisions on the longer arm of the beam marked with Roman numerals from X. to XXXX. (probably Roman pounds), and with a V. on the half of each decimal series, the smaller subdivisions being also marked. The inscription on the shorter arm of the beam (shown in a separate and enlarged figure) denotes its having been proved at the Capitol in the 8th of Vespasian Emperor Augustus, and in the 6th Consulate of Titus Emperor Augustus his son. This steelyard is consequently a duly verified standard weighing machine.

For the justness of an equal-armed balance, it is requisite (1) that the points of suspension of the pans from the beam be exactly in the same line as the centre of motion; (2) that these points be precisely equidistant from the centre of motion; (3) that the arms be as long as conveniently may be, in relation to their thickness and the weight they are intended to carry, in other words, consistently with

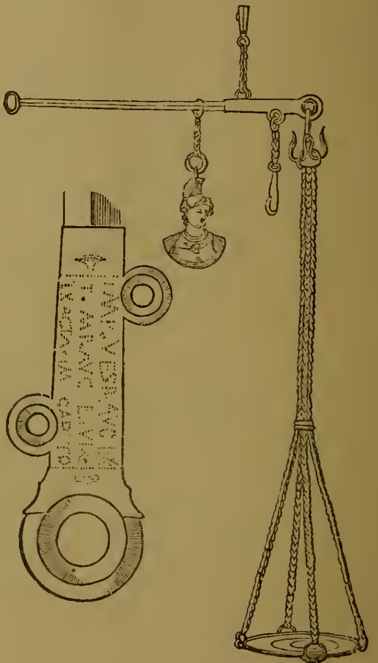

Fig. 15.—Ancient Roman Balance.

the stability of the balance; (4) that there be as little friction as possible at the centre of motion and the points of suspension; (5) that the centre of gravity of the beam be placed a little below the centre of motion.

The fulcrum upon which the beam of a balance rests is formed with a steel knife edge, and the two pans at its extremities are hung upon similar knife edges. In ordinary trade balances, these knife edges, are placed in contact with steel bearings having a spherical curve. But in the practical construction of balances of a high degree of sensibility, such as are required for scientific purposes or for the comparison of standards in which very minute differences of weight are to be determined, there are many circumstances to which attention is requisite, that may properly be neglected in balances used for commercial purposes. In such balances of precision great

* Continued from p. 491.

care is required in the adjustment of the knife edges. They are first made quite sharp, and are then slightly rounded with a fine hone or a piece of buff leather. On the regular form of this rounded edge, the excellence of the action of the balance very much depends. The central knife edge rests upon an agate or polished steel plane, whilst the two pans are suspended from agate or steel planes bearing upon the knife edges at the ends of the beam. In order to preserve the nice adjustment of the knife edges, they are never allowed to rest upon their bearings, except when weighings are made. At all other times, the beam and pans are separately supported upon a brass frame attached to the column of the balance, but moveable in a vertical direction upon it. When required to be put in action the support is gradually lowered by means of a lever handle, and the knife edges are brought upon their bearings.

The principal cause of discordances in the results of successive weighings with a balance of precision arises from the risk of the knife-edges not being brought again to exactly the same position on the plane bearings, after the balance has been stopped and again set in action. The most perfect balance is that which varies least in the points of contact between the knife-edges and their bearings during successive weighings. For the attainment of this very important requirement, the supporting frame is furnished at each of its extremities with two pins terminating in cones and made to fit exactly into corresponding conical holes in the plane bearings, at each of the extremities of the beam. The pins and holes are in a line normal to the axis of the beam. The points of these four cones are all in the same horizontal plane. As the movement of the supporting frame in a well-constructed balance of precision is always in the same vertical line, being guided by a vertical rod fitted to a cylindrically drilled hole in the column of the balance, the knife-edges and their bearings are always brought into contact in the same relative positions. Balances of precision are always enclosed in plate glass cases, with a view both to their preservation, and to keep the balances as far as possible from being affected in their action by draughts of air, alternations of temperature, &c.

As to the theory of the relative positions of the centre of motion and the centre of gravity of a balance, it is to

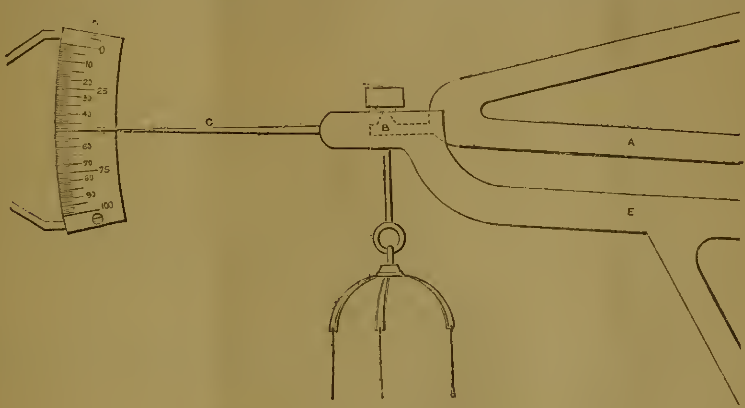

FIG. 16.—Index Scale, &c., of No. 3 Balance of Standard Department.

be remarked, (*a*) If the fulcrum be placed in the centre of gravity of the beam, and the three edges be all in the same right line, the beam of the balance will have no tendency to one position more than another, but will rest in any position in which it may be placed, whether the pans be suspended to it, or not, and whether the pans be empty or equally loaded. (*b*) If the centre of gravity of the beam, when level, be immediately above the fulcrum, it will upset with the smallest action; that is to say, the end which is lowest will descend; and it will descend with the greater velocity, according as the centre of gravity is higher, and the points of suspension less loaded. (*c*) But if the centre of gravity of the beam be immediately below the fulcrum, the beam will not rest in any position but when level; and if disturbed from that level position, it will vibrate, and at last come to rest in a horizontal position. Its vibrations will be quicker, and its tendency to the horizontal position stronger, the lower the centre of gravity, and the less the weight upon the points of suspension.

Again, as to the relative position of the central knife edge, which constitutes the fulcrum of the beam with the line joining the two outer knife edges, which form the points of suspension, it is further to be remarked, (1) If the fulcrum be below the line joining the points of suspension, and these be loaded, the beam will upset, unless prevented by the weight of the beam tending to produce a horizontal position, as shown in (*c*). In such case, small weights will form an equipoise. In case of (*a*), a certain exact weight will rest in any position of the beam; and all greater weights will cause the beam to upset, as in (*b*). (2), If the fulcrum be above the line joining the points of suspension, the beam will come to its horizontal position, unless prevented by its own weight, as in (*b*). (3) If the centre of gravity be nearly in the fulcrum, all the vibrations of the loaded beam will be made in lines nearly equal, unless the weights be very small, when they will be slower. The higher the fulcrum the quicker will be the vibrations of balances, and the stronger the horizontal tendency.

It is thus evident that the nearer the centre of gravity of the beam is to the centre of motion, the more delicate will be the balance, and the slower the vibrations. The tendency to a horizontal position is therefore increased by lowering the centre of gravity, in which case it will also require a greater additional weight to cause it to turn or incline to any given angle, and it is therefore less sensible with a greater load. The fixing of the centre of

motion in a balance is consequently of peculiar importance, for on this depends the ease with which it will be affected by a smaller weight, and the readiness with which the beam will return to a horizontal position. And it will be seen that the best position of all is that in which the centre of motion is a little above the centre of gravity. Even in this, it should be proportioned to the distance of the weights from the fulcrum, and the amount of the load, which can only be attained in different beams by practice and experience. In order to regulate the centre of gravity in balances of precision, they are made to carry a small weight either over or under the centre of motion, which is moveable by means of a screw.

From what has been said it would appear that if the arms of a balance be unequal, weights which form an equipoise will be unequal in the same proportion. But although for many purposes the equality of the arms of a balance is advantageous, yet a balance with unequal arms will weigh just as accurately as one with equal arms, provided the standard weight itself be first counterpoised, then taken out of the pan, and the weight to be compared be substituted and adjusted against the counterpoise. Or when proportional quantities only are required, they may be weighed against standard weights, taking care always to put these weights in the same pan. But in this case it is indispensable that the relative lengths of the two arms of the beam continue invariable. For this purpose, either the three knife-edges should be truly parallel, or the points of suspension and support be always in the same part of the knife-edge.

If the beam of an equal armed balance be adjusted so as to have no tendency to any one position, as in (*a*), and the pans be equally loaded, then if a small weight be added to one of the pans, the balance will turn, and the point of suspension move with an accelerated motion, similar to that of falling bodies, but very nearly as much slower in proportion as the added weight is less than the whole weight borne by the fulcrum. The stronger the tendency to a horizontal position in a balance, or the quicker its vibrations—see (*c*) and (2)—the greater additional weight will be required to cause it to turn or increase to any given angle. If a balance were to turn with $\frac{1}{10000}$ part of the weight, it would move at the quickest, 10,000 times slower than a falling body; that is to say, the pan containing the weight, instead of falling through 16 ft. in a second of time, would fall only through $\frac{1}{50}$ part of an inch; consequently all accurate weighing must be slow.

Long beams have been generally recommended because the quantity of motion in a given body varies as its distance from the fulcrum; and therefore the greater the distance, the most distinguishable will be the motion arising from any small difference between the weights compared. On the other hand, there are certain advantages in the quicker angular motion, greater strength, and less weight of a short beam.

The pans of a balance should be suspended in such a manner that in all positions the corresponding cords or rods may be parallel to one another; else the weights, though equal, will not be in equilibrium.

In ordinary commercial balances, the preponderance of either pan is indicated by a slender rod attached to the beam immediately over its centre of motion in a line perpendicular to the axis of the beam, and moveable freely between the two forks of the handle. It is called the tongue of the balance, and the degree of preponderance of either pan is shown by the greater or less deviation of the tongue from its normal vertical position. In balances of precision, the index is a longer needle-rod, fixed either in a line perpendicular to the axis of the beam, and below its centre of motion, or in a line in continuation of its axis. In both cases the pointer moves along a graduated index. But an index placed perpendicular to the beam affects its equilibrium when turning from its horizontal position; the momentum of the index being measured by its weight multiplied with the distance of its centre of gravity from a line perpendicular to the horizon. The error thence arising may, however, be corrected by continuing the index-rod or counterpoising it, on the opposite side of the beam.

The finest balances of the Standards Departments have the index pointer in the line of the axis of the beam, as shown in Fig. 16, which represents the left-hand side of the balance, the right-hand side being similarly furnished with a pointer and index scale.

This is the medium size of six of the finest balances of the Standards Department, constructed by Mr. Oertling. For all weighings of standards requiring special accuracy, the highest and lowest points reached by the needle in each oscillation of the balance are read on the index scale through a telescope fixed at about 5 ft. distance, by which means each reading can be satisfactorily taken by estimation to one-tenth of a division of the scale.

Another balance of the Standards Department is one constructed by Barrow, and used by Prof. Miller for all his weighings during the construction of the new Standard pound. The knife-edges work upon quartz planes. Index scales marked on a thin and nearly transparent slip of ivory are fixed immediately above each end of the beam and oscillate with it. They are of the following form and size. These scales are illuminated by a candle

FIG. 17.—Index Scale of Barrow's Balance.

placed at a little distance either in front of or behind the balance case, a lens being interposed; and they are viewed through compound microscopes having a single horizontal wire fixed in the focus of the eye-piece. The microscopes are fixed to the front of the balance-case, and as the observer must necessarily be close to the microscopes during weighings, a second glass screen is interposed between him and the front of the balance-case, having openings opposite the eye-pieces of the microscopes.

The weight intended to be carried by each of these balances, and the mean value of one division of the index scale, or the weight represented by it, when the balance is fully loaded, may be seen in the following table :—

Balance.	Length of Beam.	To carry in each pan.	Mean value of 1 div. of Index Scale.
	In.	Avoir. Troy.	Grains.
No. 1	36	56 to 14 lbs., or 500 to 200 oz.	0·15
No 2	24	7 to 2 lbs., or 200 to 20 oz.	0·02
No. 3	16	1 lb. to 2 oz. or 20 to 2 oz.	0·0015
No. 4	10	1 oz. and under, 1 oz. and under	0·0008
No. 5	10	30 gr. and under.	0·0002
No. 6	20	1 kilo. and under.	0·0015, or 0·1 mgr.
Barrow's	...	1 kilo. and under.	0·005, or 0·3 ,,

There is another much larger balance which was originally constructed for weighing the contents of water of the Imperial Standard bushel, the total weight in each pan being nearly 300 lbs. The beam of this balance is of mahogany, 67¼ in. in length. With a full load, the mean value of 1 div. of the index-scale is 0·4 grain. This balance, like the other, is enclosed in a large plate-glass case.

In all these balances, the value of a division varies from time to time according to the weight in the pans, the condition of the balance, the state of the atmosphere, &c., and in all very accurate weighings it is desirable to determine the value for each comparison, by an additional weighing, after a very small weight, accurately verified and equal to a few divisions only of the balance, has been added to one of the pans, so that its effect on the reading of the index scale may be noted. The above stated values

indicate nearly those found when the balance is in good working condition, and fairly weighted.

All these balances, when in equilibrium, will turn with a very small additional weight, equal to the value of two or three divisions, placed in one of the pans. They are exceedingly sensitive, for the sensibility of a balance is to be measured by the least amount of additional weight placed in either pan that is sufficient to turn the index-pointer from its normal position, when the balance is in equilibrium, and by the greatest amount of deviation from the normal position which is produced by a very small difference in the weights.

H. W. CHISHOLM

(*To be continued.*)

CINCHONA CULTURE*

FEW subjects have been so frequently before pharmaceutical readers during the past ten or fifteen years as the efforts of the governments of Holland and Great Britain to introduce the various species of Cinchona into their respective colonies. It would be hardly possible to overrate the importance of the enterprise, and it is one that interests alike the pharmaceutist, the botanist, and the votary of economic science. The records of progress which have been made public are so scattered and unconnected, the opinions and reports so conflicting, that it has been difficult for the general reader to retain the thread of the story or to arrive at any very clear estimate of the present position and prospects of the undertaking. The earliest steps in this great experiment in acclimatisation date back to a period before that which we have had under review, but so far as results are concerned, the subject is one which pertains essentially to the past few years, and I propose to place before you, in as few words as may be, and unencumbered by the controversial matter with which its literature abounds, an outline of the beginning of the enterprise and of its present practical aspect.

The initiative in Cinchona cultivation was taken, as you well know, by the Dutch Government, whose efforts were directed to its introduction into the Island of Java. The first Cinchona trees which were sent out to that colony were a few specmens of *C. Calisaya* † raised from seeds collected by M. Weddell in Bolivia, and forwarded by a firm of nurserymen in Paris in exchange for rare Javan plants. In the same year, 1852, the Dutch Government were induced to send M. Hasskarl, a gentleman previously attached to the Botanic Gardens at Buitzenorg, on a mission to South America, for the purpose of collecting plants and seeds. During the two years following M. Hasskarl pursued his labours, and succeeded in forwarding consignments from some parts of Peru, the Cinchona districts of Bolivia being for the most part closed against him; and his efforts were supplemented as to the New Granada species by the assistance of Dr. Karsten. The resulting collections were sent in part direct to Java, and the remainder to Amsterdam for re-shipment. I need not dwell on the mishaps and disappointments inevitable in so new and difficult an enterprise—it is sufficient to note that within three or four years, that is by the middle of 1856, upwards of 250 plants, almost exclusively of two species, *C. Pahudiana* and *C. Calisaya*, were flourishing in the Java plantation as the outcome of the expedition. In the same year, with wise forethought, an accomplished chemist, Dr. De Vrij, was sent out to conduct chemical observations on the growing barks.

We may pass over the long series of troubles that attended the early efforts of those in charge of the trees, the ravages of insects, the destruction of youug plants by rats, the devastation committed by wild cattle and rhinoceroses, and, above all, the difficulties dependent on climate, which eventually necessitated the transplantation of nearly the whole of the trees from the locality first chosen, on the north side of the mountain range, to one with a southern aspect. We will pass on, I say, to the year 1863, and we shall find that the total number of Cinchona trees in Java was then 1,151,810. Of these about 99 per cent. were of the species know as *C. Pahudiana*, the remainder comprising about 12,000 of *C. Calisaya* and trifling numbers of four other species. This proportion was unfortunate, for the bark of *C. Pahudiana* was found to be deficient in alkaloids, and therefore supposed to be valueless, and by decrees dated 1862 and 1864 its further culture was ordered to be forthwith stopped.

We may now turn to the steps taken by the British Government in the same direction.

Dr. Ainsley, in his work on "Materia Medica," was perhaps the first to suggest the idea of the acclimatisation of the Cinchona in India, and, as early as 1839, Dr. Forbes Royle especially indicated the Neilgherry and Silhet mountains as eligible for the experiment. Appeals were subsequently made to the East India Company by Mr. Grant and Dr. Falconar, with the object of inducing them to take up the matter, and in 1852 instructions were sent to the British consular agents in South America to endeavour to procure seeds of the various species, but without much real effect. Dr. Royle, as Reporter on the Products of India, continued to urge the subject on the attention of Government up to the time of his death, and eventually, in 1859, at the instance of his successor in office, Dr. Forbes Watson, the services of Mr. Clements R. Markham were called into request by the home authorities.

Mr. Markham proposed a fourfold expedition to South America, and his scheme was at last sanctioned by the Secretary of State for India, and ordered to be carried out. The first portion of the expedition was directed to Bolivia and Caravaya, the region of *Cinchona Calisaya* and *C. micrantha* (var. *Boliviana*). Secondly, Huanuco and Huamalies were to be searched for *C. nitida* and *C. glandulifera* Thirdly, Cuenca and Loxa in the Republic of Ecuador for *C. Chahuarguera*, *C. Uritusinga*, and *C. Condaminea*; and lastly, New Granada as the habitat of *C. pitayo* and *C. lancifolia*. Mr. Pritchett and Mr. Spruce were appointed coadjutors to Mr. Markham, and the expeditions set out in 1859, the latter gentleman proceeding to the northern part of Bolivia, the district of the yellow barks; Mr. Spruce to the mountain region of Chimborazo, in quest of red cinchonas; Mr. Pritchett taking the grey bark forests of Huanuco, in the north of Peru. The perils encountered by these travellers, the hardships they endured, the disappointments they suffered, form a chapter in the history of travel. But illness and privation, bad roads, and even native jealousies left unaffected the general success of the expedition, and though, unfortunately, the plants collected at great risk by Mr. Markham, including many of the best species of Bolivia, perished in the Red Sea in their transit to India, leaving no survivors, it is to the work accomplished by these three enthusiastic labourers that we owe the basis of our present Cinchona plantations. In 1860, the Ootamacund station was established, and the following year the number of young Cinchona trees was reported to be 1,128. Under the excellent care of Mr. McIvor these had been increased in 1863, the date to which I have brought my account of the Java plantations, to 248,166.

It is no part of my purpose to enter into minutiæ of history, nor to do more than associate with the first steps in Cinchona culture the names of Messrs. Hasskarl and Markham, Spruce, and Pritchett as travellers, those of Dr. De Vrij and Mr. John Eliot Howard as advisers in technical details, and more recently, Messrs. McIvor and

* From the Address delivered at the Pharmaceutical Conference, Bradford, by Henry B. Brady, F.L.S., F.S.C., President.

† My friend, J. E. Howard, F.L.S., to whose kind revision subsequent paragraphs owe any scientific value they possess, tells me that, accuratel speaking, these were *C. Calisaya*, and var. *Josephiana*.

Broughton, who have been conspicuous, so far as India is concerned, in the rapid development of the enterprise.

The efforts of our own Government have not been confined to India, but localities have been sought in other parts of the world where natural conditions seemed to favour the chance of success in the introduction of quinine-yielding trees, and at the time I speak of (1863) there were under the care of Mr. Thwaites in Ceylon upwards of 20,000 young Cinchona plants. Jamaica also had made a successful beginning, and the authorities of several European countries were considering how far their respective colonies might be utilised to the same end, though but little decided action beyond what I have stated had been taken.

The ten years that have intervened need not detain us, but having noticed the origin, we will turn at once to the practical aspect of the subject at the present time.

The latest official return places the number of Cinchona trees in cultivation in the Island of Java at two millions.

I can find no published account of the exact extent of the British plantations at the present time. My latest information I owe to the kindness of C. R. Markham, F.R.S., of the India Office. It is contained in the Parliamentary Blue-book of August 1870, and refers only to the Madras and Bengal Presidencies. This gives the total number of Cinchona plants growing on the Neilgherries in January of that year at 2,595,176, of which nearly one-half (1,143,844) were permanently planted out.* The number at Darjeeling in the Bengal Presidency in March 1870 is stated at 2,262,210, of which a million and a half were in permanent plantations.

Of the extent of the plantations in Ceylon and Jamaica I know nothing, but reports from time to time state that they are prospering. It is needless to refer to the experiments in cultivation in the south of Europe, the Caucasus, Brazil, the Philippines, or Australia, as these are not yet sufficient in extent to have any practical significance.

The relative value of the bark produced by the various species and varieties of Cinchona is a question that has received close attention, and perhaps cannot be considered settled until something more like uniformity in the subdivision and nomenclature of the genus prevails. Plants regarded as merely varieties of the same species yield widely differing proportions of alkaloids, and the subject is further complicated by considerations as to the possible effects of cultivation and of different climatal conditions. . . . .

The barks now being produced in the Dutch and British colonies are referrible to five species, viz.:—

C. Calisaya, of which, as I have said, only a small proportion realises expectation in its yield of quinine;

C. Hasskarliana (called a bybrid), which appears to be of little value in respect of alkaloids;

C. Pahudiana, deficient in the same particulars, but producing a bark which finds a ready market for pharmaceutical purposes;

C. officinalis, which, in British India,* appears to be the most generally satisfactory; and

C. succirubra, which, notwithstanding certain exceptional samples, has not turned out altogether well. . . . .

I can say little about the West Indian plantations as to extent, but the quality of the bark they produce is encouraging. Mr. Howard reports that the chemical examination of barks from Jamaica is "highly satisfactory as regards the prospects of Cinchona culture in that island."

Various questions are still pending:—the influence of manures on the chemical constituents of the trees, the various methods of removing the bark from the tree, and the encouragement of renewal by the processes of stripping and mossing, and many others of like importance, the solution of which must be left to time, and need not occupy our consideration here.

* Since this was written I have received a copy of a return which is believed to represent the actual number of Cinchona trees in the Government plantations in the Neilgherries at the present time. It shows an increase of 12,330 "planted out," and is as follows:—

Crown barks (*C. officinalis*)	508,878
Red barks	579,938
Yellow barks	33,850
Grey barks	28,759
Other species ... :	4,749
	1,156,174

In addition to these it must b recollected that the Government had up to 1870 distributed upwards of 178,000 trees from the Neilgherry nurseries, as well as nearly three hundred ounces of the seeds of various species, to private individuals disposed to plant on their estates. After all, when the experimental stage of such an undertaking is over, private enterprise would seem to be its safest basis. A Parliamentary paper on the progress of India in 1872, just issued, gives the total number of plants in the Neilgherry plantations as 2,639,285, but this probably includes the very young trees still in nurseries. I have no particulars beyond what appear in a paragraph in the *Times*.

* This limitation is at present necessary. Dr. De Vrij's late paper on Jamaica barks ("Pharm. Journal," August 16, 1873) shows the produce of *C. officinalis* in that island to be very deficient in quinine, inferior indeed to *C. Pahudiana*, whilst a still later communication confirms Mr. Howard's opinion as to the richness of Indian-grown specimens.

DONATI

SCIENCE, and more particularly astronomy, has recently sustained a serious loss in the death of Prof. G. B. Donati, Director of the Royal Observatory of Arcetri, near Florence, and Professor of Astronomy in the Royal Institution of that city.

On his return from Vienna, where he had represented Italy at the International Meteorological Congress, he was seized by a severe attack of Asiatic cholera, to which in a very short time he fell a victim, dying at his villa near the Observatory, on the morning of the 20th of September last, being only forty-seven years of age. He was born at Pisa in 1826. In 1852 he began his astronomical career at the Observatory of Florence, and by his talents, his attainments, and his indefatigable industry, rapidly gained the esteem and admiration of the learned, attaining a well-merited fame, not so much by the discovery of new comets—among which the most remarkable was that of 1858, to which he bequeathed his name—as by the important observations which he made and published. Of these we need only mention his observations on the study of the spectra of the stars, by which work he successfully inaugurated in 1860 one of the most important branches of physical astronomy, namely, the spectroscopy of celestial bodies.

In 1864 he succeeded Prof. G. B. Arnia as Director of the Observatory, after which much of his time and energy were devoted to the establishment of an observatory for Florence and for Italy, which should be completely adapted to the present exigencies of Science, both as regards astronomy and terrestrial physics.

He was in no way discouraged by the serious difficulties of this undertaking, but, inspired by a true love of Science, he overcame them all, insomuch that in a short time, under his active and keen-sighted superintendence, the new observatory was erected on the hill of Arcetri; an observatory which, by the excellence of its position, as well as by the convenience and solidity of its construction, has guaranteed for astronomy and terrestrial physics the most important advantages in every branch of observation.

The observatory was already in working condition, and an important series of observations had been commenced when Science was robbed, by a premature death, of one of her most valued worshippers, who was thus cruelly cut off just as he had entered upon a brilliant career, in which, had he lived, he would certainly have greatly augmented his fame, and shed glory on the Observatory of Arcetri.

Prof. Donati had already commenced a series of notes from the new observatory by the recent publication of

some most careful observations of his own on the luminous phenomena of the great Polar aurora of the 4th to the 5th of February, 1872; and we had hoped that other important observations by the illustrious Italian astronomer would, to the great advantage of Science, have been published in the future Notes issued from that scientific establishment.

NOTES

WE regret to have to record the death of two notable men this week. The one is Sir Henry Holland, Bart., M.D., F.R.S., &c., who died on Tuesday, the 28th inst., at the age of 85 years. Sir Henry had caught cold on returning from Paris, which, in spite of his wonderfully robust constitution, proved too much for the veteran traveller. The other is Mr. Albany Hancock, the distinguished anatomist, who died on the 24th inst. He was a medallist of the Royal Society, though not a Fellow. We hope shortly to give memoirs of both men.

SIR ROBERT MACLURE, C.B., so well known in connection with Arctic discovery, died on the 17th inst., at the age of 66.

SIR SAMUEL BAKER was announced to appear before the Geographical Society on Monday first, and give an account of the geography of the country he has lately visited; but we regret very much to hear that illness will prevent him from fulfilling this and other engagements. He has been suffering from inflammation of the lungs.

PROF. FLOWER, we regret to hear, has been compelled to spend the winter in Egypt on account of the state of his health.

DR. J. EMERSON REYNOLDS has been elected Professor of Chemistry to the Royal College of Surgeons in Ireland. The College of Surgeons is to be congratulated on this appointment. Dr. Reynolds will, we believe, still hold his appointment of Keeper of the Minerals and Professor of Analytical Chemistry to the Royal Dublin Society.

MR. JOHN STUART MILL has left his herbarium of European plants to Kew.

WE are informed that the authorities of the Jardin des Plantes, of Paris, have acquired the valuable collection of books on Natural History belonging to the late M. J. Verreaux, and also his private collection of Sugar birds (*Nectariniidæ*), which includes many unique specimens.

IN connection with St. John's College, Cambridge, there will be offered for competition an Exhibition of 50*l.* per annum for proficiency in Natural Science, the Exhibition to be tenable for three years in case the exhibitioner have passed within two years the previous examination as required for candidates for honours: otherwise the exhibition to cease at the end of two years. The candidates for the Natural Science Exhibition will have a special examination (commencing on Friday, December 12, at 9 A.M.) in (1) Chemistry, including practical work in the Laboratory. (2) Physics, viz., Electricity, Heat, Light. (3) Physiology. They will also have the opportunity of being examined in one or more of the following subjects, (4) Geology, (5) Anatomy, (6) Botany, provided they give notice of the subjects in which they wish to be examined four weeks prior to the examination. No candidate will be examined in more than three of these six subjects, whereof one at least must be chosen from the former group. It is the wish of the Master and Seniors that excellence in some single department should be specially regarded by the candidates. They may also, if they think fit, offer themselves for examination in any of the Classical or Mathematical subjects. Candidates must send their names to one of the tutors fourteen days before the commencement of the Examination. The tutors are Rev. S. Parkinson, D.D.; Rev. T. G. Bonney, B.D., and J. E. Sandys, Esq., M.A.

THE Royal Horticultural Society of Tuscany has announced an International Horticultural Exhibition to be held at Florence from May 17 to 25, 1874, and has also issued the programme of an International Botanical Congress to be held on three days during the Exhibition. A very large number of prizes, including 100 gold medals, are offered for collections of plants or single plants, which are included in 248 different classes; and among other objects for which prizes may be obtained are bouquets, botanical drawings, models, garden tools and ornaments, garden structures, manures, herbaria, specimens of timbers, &c. The Congress will be opened by the president, Prof. Parlatore; excursions to the neighbourhood of Florence and the principal gardens will be inaugurated, &c.; and among the subjects proposed for discussion, *inter alia*, are the following:—On the duration of dormant vitality in plants, and on the means of restoring it; on the causes of the movements in leaves; on the acclimatisation of perennial plants; on the analogy between the reproductive organs of flowering and (so-called) flowerless plants; on the general occurrence, or otherwise, of cross-fertilisation, and on the durability of the vitality of pollen; on the nature and functions of the gonidia of lichens: on the nature and origin of Bacteria; on the possibility of establishing rules for a rational distinction between the groups called species, race, variety, &c.; on the value to be set on the determination of fossil plants, &c.; on the character and origin of Alpine floras, and especially on the causes which have limited their extension. The Horticultural Society of Tuscany seem determined to do everything they can to attract visitors, who must send their names to the president or secretary at the Musée Royale de Physique et d'Histoire Naturelle at Florence; and altogether botanists and horticulturists seem likely to have a good time of it.

AN effectual remedy for the devastations committed on the vines by the *Phylloxera vastatrix* is said to have been discovered by MM. Monestier, Lautand, and D'Ortoman, of Montpellier. It consists in placing in the ground, close to the root of the infected plant, an uncorked tube containing about 2 oz. of bisulphide of carbon. The vapour from the bisulphide in a short time permeates the whole of the ground about the root; the vapour is not, like the liquid itself, injurious to the plant, but is immediately fatal to the insect. Care must be taken not to spill any of the liquid on the roots of the vine.

THE following subjects for prizes to be awarded in 1874 hav been proposed by the Batavian Society of Experimental Philosophy:—1. To discover if there exists in the molecular state of bodies, modifications other than those caused by temperature, which are such as to give for the same body, different spectra. The Society wishes that this inquiry should bear chiefly on the magnetic condition of bodies. 2. To find out by new experiments if the vapour of water exercises on radiant heat an absorbant effect much more powerful than dry atmospheric air as Mr. Tyndall maintains; or if there exists no difference in this respect between dry and moist air, as M. Magnus maintains. The Society desires that the new experiments which it asks for be conclusive and enable it to decide between the two opinions. 3. To determine what influence the pressure which is put upon an electrolyte has on electrolysis, and how far in this case is the principle of conservation of energy confirmed. It is wished that this inquiry bear on three liquids at least, to be chosen by the competitor. 4. To determine the resistance of the liquid amalgams of zinc and gold to the galvanic current. Six at least of each of these amalgams, in various proportions, ought to be examined. 5. A prize is proposed for new experiments which will enable a

certain decision to be come to on the opinion advanced by M. Gaugain as probable, viz. that voltaic electricity is propagated by matter, while induced electricity is propagated by ether.

THE German expedition for the exploration of the Libyan desert is expected to start from Europe about the end of November, and from Egypt early in December, and it is thought that the first reports may accordingly be looked forward to about Christmas. The leader of the expedition is Dr. Gerhard Rohlfs.

FATHER SECCHI, we are glad to see, has received permission from the Italian Government and Cardinal Antonelli to remain at the Royal College of Astronomy.

AMONG the societies concerning which we have received information since the publication of our list last week, is the Working Men's College Field Club, of which Prof. Flower is president. It meets in the Museum of the College in Great Ormond Street, has been in existence only five months, but appears from a reports before us to be in good working trim. It has meetings at which papers are read, courses of lectures by well-known scientific men, and several field-days each month. These field-days seem generally to be Saturday and Sunday, and we only wish that working-men generally put their Saturdays and Sundays to such an excellent recreative use.

WE congratulate the Sunday Lecture Society on the excellent beginning, to be made next Sunday, of their winter course of lectures. Dr. Carpenter, we see, is to give a series of two lectures on the brain; and we think the society ought to consider whether it would not be advisable to have more connected series of lectures than they have hitherto had.

IN a final letter to yesterday's *Daily Telegraph*, Mr. George Smith concludes the account of his Assyrian Expedition. Altogether both Mr. Smith and the *Telegraph* are to be congratulated on the results of the enterprise.

THE following "Science Lectures for the People," are announced to be delivered at the Memorial Hall, Manchester; the Hulme Town Hall being now required for other purposes:— Wednesday, Oct. 29, "Polarised Light," illustrated by experiments in the electric light, by Wm. Spottiswoode, F.R.S., Treasurer of the Royal Society. Nov. 5, "How Flowers are Fertilised," by A. W. Bennett, M.A., Lecturer on Botany, St. Thomas's Hospital, London. Nov. 12, "On Parasites and their Strange Uses," profusely illustrated, by T. Spencer Cobbold, M.D., F.R.S. Nov. 26, "Animal Mechanics," illustrated by experiments with the electric light and the oxy-hydrogen lantern, by S. M. Bradley, F.R.C.S. Dec. 3. "The Senses," by Prof. Croom Robertson. Dec. 10, "On Muscle and Nerve," illustrated by experiments with the electric light and the oxy-hydrogen lantern, by Prof. Gamgee, F.R.S. Dec, 17, "The Time that has elapsed since the Era of the Cave Men of Devonshire," by Wm. Pengelly, F.R.S.

THE French Association, as is known, is to meet at Lille in 1874. Among the many towns which desire to be favoured with its presence in 1875 is Nantes, the Municipal Council of which has already devoted 10,000 francs to defray the preliminary expenses of the session, should it take place there.

ACCORDING to *La Nature* the volcano of Mauna Loa, in Hawaii, is at present in full eruption.

A MICROSCOPIC SOCIETY has recently been founded at Melbourne.

LAST Thursday the whaler *Erik* arrived in Dundee, having on board R. W. D. Bryan, who was astronomer to the *Polaris* Expedition; B. Manch, seaman; and J. W. Booth, fireman. All the men were in excellent health. On Friday the *Ravenscraig* arrived at Dundee, having on board one of the boats ingeniously constructed by Mr. Chester, in which the castaways effected their escape from their winter quarters. It is about the size of a whaling-boat, and somewhat similarly shaped.

THE *Journal of the Society of Arts* gives, from the annual report published by the Minister of Public Education, the following particulars respecting education in Italy during the scholastic year 1872-73:—The number of students registered at the Royal Universities was 5,614, and in addition to this number 1,333 persons were allowed to attend the course of lectures, making in all 6,497. At the Universities of Camerino, Ferrara, Perrugia, Urbino, 284 students and 22 non-students, in all 806, attended the course of lectures. At the Royal Institute of high studies at Florence the number of students was 214. The Literary and Scientific Academy of Milan numbered 26. At the Royal School of Application for Engineers the number of students was 173, and at that at Naples 185. The Technical Institute of Milan was attended by 209 students, and the Normal School of Pisa by 41. 295 students were registered at the schools of Veterinary Science of Milan, Turin, and Naples. The royal lyceums are 79 in number, with 4,228 pupils; the royal gymnasiums 104, with 8,462 pupils. In the royal colleges, which are 26 in number, there were 2,208 pupils. The following schools received subsidies from Government:—32 in Piedmont, 67,290 francs; 19 in Lombardy, 49,810 fr.; 10 in Venetian provinces, 16,550 fr.; 24 in Emilia, 52,800 fr.; 14 in Tuscany, 31,200 fr.; 17 in Marshes, Umbria, and Roman provinces, 20,800 fr.; 54 in Neapolitan provinces, 90,350 fr.; 5 in Sicily, 6,200 fr. The number of elementary schools throughout the kingdom was 41,713 (being 3,413 more than were opened during the previous year). Of this number 21,353 were for boys, and 16,280 for girls. 33,556 were public and 8,157 private schools. The number of pupils attending those schools during the scholastic year 1872-73 was 1,723,007, showing an increase of 145,853 on the number of the previous year; of this 960,517 were boys, and 762,490 girls. The total number of pupils attending the public schools was 1,545,820, and those of the private schools 177,187. The total number of teachers in these schools was 43,420, being an increase of 3,102 on the number of the previous year. Of these 23,212 were teachers in the boys' schools, and 20,211 in the girls' schools; the public schools being conducted by 34,309 teachers, and the private by 9,114.

WE have received the Catalogue of the publications of Gauthier-Villars, of Paris, for April, May, and June of this year. It contains the publications of most of the scientific societies of France, beside a number of original works in mathematics, physics, engineering, &c., which recommend it to the attention of scientific men. A few more foreign catalogues have also come to hand, which we would recommend to those who wish to know what is being published on the Continent; no doubt the publishers would be glad to send these catalogues to any one asking for them:—Catalog des Antiquar. Bücherlagers von Fidelis Butsch Sohn (Augsburg, 1874, *sic.*); A catalogue of works in Anatomy and Physiology, and Medicine generally, which belonged to the late Dr. Fahle, of Altona (T. O. Weigel, Leipzig); the same bookseller has sent a Catalogue of standard works in all departments of Science.

WE are glad to see that the *Quarterly Journal of Education*, which is shortly to become a monthly, has opened its columns to a correspondence upon questions relating to science-teaching.

WE have received a separate reprint from the "Proceedings of the Geologists' Association" of Mr. D. C. Davies' valuable paper on "The Overlapping of the Several Geological Formations of the North Wales Border."

THE United States Signal Service has recently constructed a telegraph line to the summit of Pike's Peak, in Colorado, which is said to be the highest point reached by any line in the United States, or perhaps in the world. The height is said to exceed 11,000 ft. Regular reports as to the weather are to be sent to Washington thiee times daily.

THE additions to the Zoological Society's Gardens during the past week include an American Cross Fox (*Canis fulvus*), a Golden Eagle (*Aquila Chrysaëtus*), and a Virginian Eagle Owl (*Bubo virginianus*), from North America, presented by Capt. D. Herd; a Mexican Deer (*Cervus mexicanus*), from Porto Rico, presented by Mr. W. Isaacson; two Sand Badgers (*Meles ankuma*), from Japan, presented by Lieut. Hon. A. C. Littleton; a Black-eared Marmoset, (*Hepale penicillata*), from Brazil, presented by Mr. C. Hawkshaw; a Spotted Hyæna (*Hyæna crocuta*), and two Bronze-winged Pigeons (*Phaps chalcoptera*), born in the Gardens; two Rheas (*Rhea americana*), from S. America, deposited; two Chilian Tinamous (*Rhynchotus perdicarius*), three Banded Tinamous (*Crypturus noctivagus*), and two Obsolete Tinamous (*C. obsoletus*), from S. America, received in exchange.

---

*ORIGINAL RESEARCH AS A MEANS OF EDUCATION**

II.

IT is the greatest possible mistake to suppose—as, unfortunately, many yet do—that a scientific education unfits a man for the pursuits of ordinary professional or commercial life. I believe that no one can be unfitted for business life or occupations by the study of phenomena, all of which are based upon law, the knowledge of which can only be obtained by the exercise of exact habits of thought, and patient and laborious effort. I dare say many who have had a scientific education make bad men of business, but so do many who have not had such an education; it is not the scientific education which has spoilt them. Even more directly does the value of scientific education bear upon professional and manufacturing life. The medical man's success depends mainly upon the exercise of faculties which are pre-eminently called forth, and strengthened in original scientific investigations. The manufacturer who aspires to something more than following the rule-of-thumb work of his predecessors, requires exactly these habits of mind which are developed by original research. If the brewer, the calico-printer, the dyer, the alkali-maker, the metallurgist wish to make any advance of their own in their respective trades, they cannot do so without the exercise of powers which can only be gained by the prosecution of original inquiry. Doubtless many—nay, even most—of the great discoveries and improvements in the arts and manufactures may have been made by men who have been self-taught. But these men have acquired for themselves, by slow and difficult steps, the same habits of exact observation, patient and laborious devotion, and manipulative or constructive skill which the modern student of science may, at any rate to a very considerable extent, gain in his college course. So valuable is this kind of education found to be, that in Germany, where it is most practised, the chemical manufacturers now refuse to take young men into their works unless they have not merely had a scientific education, but also have prosecuted original investigation.

If, then, education in its widest sense has for its objects, as I presume will be generally allowed, the training of the mind and faculties in such a way as most fully to qualify the possessor to discharge with benefit to mankind his duties in after-life, surely plans for the encouragement of original scientific research should form no inconsiderable portion of the work of every institution professing to deal with the higher education of the country. And yet when we come to look at the provision made for encouraging original research, either at our older or at most of the more modern seats of learning, we are astonished to find that this essential provision is almost altogether ignored. At Oxford and Cambridge thousands of pounds are each year lavished upon the encouragement of classical and mathematical attainments, whilst the claims of original research can scarcely be said to be recognised. Hence these highly endowed universities, whilst they are justly celebrated for their critical faculties, have ceased to represent, in any one direction, the productive power of the country.

Original research, the true life-breath of civilisation, does not in England, as is the case in Germany, look to the universities as the nurseries where its young shoots shall be tended and cherished, for there, at present, its value is scarcely recognised. Indeed, Sir William Thompson has expressed his opinion that the system of examinations at the universities has a tendency to repress original inquiry, and exerts a very injurious effect in obstructing the progress of science. The time is, however, not far distant when this want of appreciation of the value of original research will be a thing of the past, and when the universities will vie with each other in encouraging this mainspring of progress, and in honouring more those whose lives are devoted to this high calling. Owing to the want of means of promoting original investigation in our great seats of learning, the scientific activity of the country has found vent through other channels. No want of encouragement can repress really great minds or powerful wills. Manchester can boast the names of many men who, in spite of want of university aid, have done much for science. Who, for instance, in the whole scientific annals of Oxford, can be placed on a footing of equality with Dalton or Joule? These men are, however, great in spite of our systematic negligence of the subjects, the mastery over which has made their names immortal.

If, in the face of so much that is discouraging in this want of recognition of science, England has still no reason to fear the comparison of her great men of science with those of other countries, we may feel sure that our position among the nations will be raised when the Government, our universities, and the country at large become alive to their duties as regards the encouragement of original scientific research, and when the number of able men who devote themselves to this pursuit shall thereby be largely increased. Much assistance in this direction may confidently be expected from the Royal Commission on Scientific Instruction and the Advancement of Science, of which his Grace our President is chairman, and which has lately published its third report on the progress of scientific education and research in the two old universities. In this report, the importance, from a national point of view, as well as an educational instrument of original research is fully recognised, whilst the means of enabling the universities to take their due share in the management of this branch of human activity is suggested. The evidence given before this Commission by Sir Benjamin Brodie, Prof. Frankland, Dr. Carpenter, and other competent authorities, is of the most decided and unanimous character, and the opinion thus strongly expressed must ere long produce its effect.

The importance of fostering scientific research in connection with higher education is, however, now well understood to the authorities of this college. Very considerable facilities for carrying out original work are given both to the teachers and to the pupils, whilst in the appointment of the professors special weight is always laid on their power of conducting scientific research. In my department, which has now been organised for many years, I make bold to say that we have not been behind any chemical laboratory in this kingdom in the original work we have produced. The physical laboratory, which has only recently been inaugurated, has already, under the care of its talented Director, whose original researches are valued wherever Science is appreciated, done valuable work, and the new department of practical physiology which has just been established will doubtless soon bear fruit of a similar character. In the biological sciences our teaching resources have hitherto been limited; but although this has necessarily prevented the prosecution of research by the students, the professors of this department have long been distinguished for original investigation in their special branches.

To assist in developing in the practical community the appreciation of scientific research, and owing to the liberality of Manchester men and to the wise advice of Prof. Frankland, who then occupied the chair which I have now the honour to hold, a scholarship for original chemical research—our Dalton Chemical Scholarship—was founded in 1853 as a testimonial, and a fitter one could not have been proposed, to our great townsman. The establishment in England of a scholarship for excellence in original research was, twenty years ago, a circumstance without a parallel, but in spite of the novelty of the experiment, time has fully proved the wisdom of the course which its originators adopted. We can already point to a fairly long list of men who have taken our Dalton Scholarship, who now hold high and

* Concluded from p. 539.

responsible positions in scientific, manufacturing, and official life; and these men will all acknowledge the benefit conferred upon them by the training they received when competing for the scholarship, and whilst occupied for the first time in their lives in carrying out an investigation on some original subject.

On the model of our Dalton Chemical Scholarship, an important physiological scholarship has lately been founded in this College by Mr. Robert Platt; the conditions of tenure involve the prosecution of an original investigation in physiology; and it is to be hoped and expected that this scholarship will do as much to stimulate the study of physiology amongst us as the Dalton has certainly done in the case of chemistry. The establishment of similar scholarships in the branches of physics and biology is much to be desired, and benefactions made for these special purposes will assuredly prove of the greatest value.

It is unnecessary for me to point out the direct applications which the knowledge and experience gained in the laboratory receive in the arts and manufactures dependent upon chemical science. These everyone can see for himself. The ordinary routine work of the alkali maker, the dyer, the brewer, the calico printer, calls immediately for chemical knowledge, and manufacturers who do not yet see the value of the training afforded by original experimental investigation, are ready enough to appreciate chemical knowledge if it can show them that their drugs are adulterated or their water impure.

Concerning the exact mode by which encouragement should be given in this country to original research, opinions may differ. One proposal has lately been made by the distinguished president of the British Association (Prof. A. W. Williamson), in his able address at Bradford, which it behoves all interested in the progress of the country carefully to consider. Without attempting to discuss the details of this or other schemes, it may be well to point out those general features of the subject upon which these proposals are based.

In the first place, then, we shall agree that the measures which have to be taken must be systematic, must apply to the country at large, and must include all classes. What we need is the development of the latent intellectual resources of the country as regards science, the means of sifting out from the great mass of the people those golden grains of genius which now too often are lost amongst the sands of mediocrity. This can only be fully accomplished by a system extending from the lowest primary schools up to the highest educational establishments in the land, and therefore almost necessitates the action of Government. But whilst believing that a national system is needed in order that the potential scientific energy of the country shall become active, I for one should most strongly object to the establishment of a complete system of State education. One of our greatest safeguards and sources of national strength has been and is the freedom from Government control which our educational, municipal, and local institutions have always enjoyed; and the evils of a uniform State system as existing in France (which is such that the Minister for Education remarked with pride, that at a given moment the classes in all the Lycees in France were engaged in reading the same chapter in Cæsar's Commentaries) need only be felt to be deplored.

Secondly, it is clear that in order to be able to select from amongst the people those whose mental and physical powers fit them for ultimately advancing science themselves, the rudiments of a scientific training must be much more widely diffused than is at present the case. This can only be slowly accomplished; the methods of teaching science are only beginning to be understood, and, unfortunately, in school teaching the introduction of a scientific subject has too often been looked upon more as an amusement than as a study requiring as much or more attention and exactitude than the older subjects, one which when properly taught acts to quite as great an extent as a mental discipline. Science teachers have yet to be trained, and a system of introducing elementary science as disciplinary teaching into primary and secondary schools has yet to be made general. At the same time new institutions have to be founded in which the higher branches of the various sciences are taught and original research encouraged, and into which youths of conspicuous merit must be drafted, whilst existing colleges and universities have to be modified to suit the requirements of the time. These institutions must contain laboratories, not only for teaching purposes, but suited for scientific research, and the professors must take in a certain number of advanced students to work on original investigation. This is indeed, as Sir Benjamin Brodie points out in his evidence before the commission, an educational function of the most important character; because here scientific education is carried out to its end, and if this is not done, you stop short of the most important part of all in scientific education, for the perfection of science as a means of education is seen only in scientific inquiry. The pupils thus trained eventually pursue science as their main business in life, and become in their time teachers and professors of their subject. Thus by degrees the profession of the investigating teacher will become recognised as one in which the ablest of our youths may obtain reward and recognition, as well as satisfaction and delight, and thus the scientific power of the country will be vastly increased.

Concerning the ennobling nature of original scientific inquiry it is needless for me to say much, for although I should be the last to contend that men of science are free from the foibles and weakness common to all mankind, I think it stands to reason that the habits of mind which an investigator must cherish, are such as must raise him above the petty struggles of ordinary existence, and must, for a time at least, lift him into an atmosphere free from the cloud and smoke which too often darken the usual current of men's lives. In order to give you an idea in what original research consists, and to point out to you the interests attaching to an inquiry, the practical applications of which seem as far distant as those of a newly-discovered planetoid, I will for a few moments draw your attention to a case of the kind with which I happen to be familiar. Amongst the sixty-three different elements of which the earth, so far as we know, is made up, there are many which have been found only in the most minute quantity. Indeed, in the list of elements suspended on the wall, you will notice that a large number out of the sixty-three are marked as rare. A few only of these substances are employed in the arts and manufactures, or are known to play any part in the economy of nature; the rest are rarities of interest at present only to the scientific chemist. It would, however, be presumptuous on our part were we to assume that the existence of these bodies is a matter of no moment, for we are constantly learning that substances hitherto supposed to be useless are of the most vital importance. Hence it is obviously our duty to get to know all we can about the properties of each, even the rarest, of these elementary bodies, and especially about their relation to, and mode of action on, the other elements. It is clear, too, that as long as our knowledge of the properties of any one of these elementary bodies is inaccurate, or if mistaken views regarding any one have arisen, our science must suffer in completeness. For just as an error made in the basement of a house throws the upper storeys wrong, so a mistake concerning the size and shape of the foundation blocks of our science may render the whole chemical superstructure faulty.

In 1830 the great Berzelius fully examined a new elementary body termed vanadium, the existence of which had been previously discovered by his countryman Sefström. Having most carefully ascertained the remarkable properties of this new substance and its compounds with the other elements, Berzelius gave to vanadium and its compounds a certain chemical position and place amongst the other elements. Thus to the compound of vanadium and oxygen containing the largest proportion of the latter element, and called vanadic acid, he assigned the formula V_2O_3, meaning thereby, in the atomic language of our great townsman Dalton, that two indivisible particles or atoms of the metal are combined with three indivisible particles or atoms of oxygen; and these views, enforced by experiments of the most unimpeachable character, were for years universally adopted by chemists.

In 1858 a fact was observed by the German chemist, Rammelsberg, with regard to the crystalline form of the best known mineral containing vanadium which exhibited Berzelius's conclusions in a new light. It had long been known that substances which have an analogous chemical composition are found to crystallise in an identical form. Thus the different alums containing alumina, oxide of iron, oxide of chromium, oxide of manganese, all crystallise in octahedra; and the oxides contained in these alums have all an analogous composition; that is, the relations between the number of atoms of metal and of oxygen in each case is identical. Now, Rammelsberg found that the crystalline form of a mineral contained vanadic acid, and lead was identical with another mineral containing phosphoric acid and lead. Hence we should expect to find that the oxide of vanadium, termed vanadic acid, and the oxide of phosphorus, called phosphoric acid, possess an analogous chemical constitution. Such, however, was found not to be the case. Phosphoric acid is well

known, and, without doubt, consists of two atoms of phosphorus, united with five atoms of oxygen, whereas Berzelius only found three atoms of oxygen to two of the rare metal in vanadic acid. How is this discrepancy to be explained? We have here to do either with an exception to the otherwise general law of isomorphism, so that we may have identity of crystalline form, without any analogy in chemical composition, or Berzelius's experiments and conclusions respecting the constitution of this vanadic acid are incorrect. By experiments on the properties of vanadium and its compounds, made with much larger quantities than it fell to the lot of the Swedish chemist to work with, it was shown that something had been overlooked by him. It was proved that the substance which he supposed to be a metal was not a metal at all, but an oxide, and that vanadic acid really contains more oxygen than he believed it to contain. And what is remarkable is that this quantity of oxygen, which had been overlooked, is exactly the quantity which is needed in order to make the constitution of vanadic acid identical with that of phosphoric acid. We have to take out of each atom of Berzelius's metal one atom of oxygen in order to get the true vanadium, so that the real atomic weight of this element is less than that given to it by Berzelius by the atomic weight of oxygen, $67{\cdot}3 - 16 = 51{\cdot}3$. Thus the chemical constitutions of phosphoric and of vanadic acids are represented by the formulæ $P_2 O_5$. $V_2 O_5$. The law of isomorphism remains unassailed, and the goddess (Vanadis is a cognomen of the Scandinavian goddess Freia) who was found wandering as a waif and a stray amongst her companion elements, has been restored to her natural friends, and now forms a recognised member of a family group.

To sum up, my aim in the foregoing remarks has been to show that if freedom of inquiry, independence of thought, disinterested and steadfast labour, habits of exact and truthful observation, and of clear perception, are things to be desired as tending to the higher intellectual development of mankind, then original research ought to be encouraged as one of the most valuable means of education. And that on this ground alone, and independent of the enormous material benefits which such studies confer on the nation, it is the bounden duty not only of the Government, but of every educational establishment, and of every citizen of this country who has the progress of humanity at heart, to promote and stimulate the growth of original research amongst us.

HELVETIC SOCIETY OF NATURAL SCIENCES

THE fifty-sixth annual meeting of this society was held on the 18th, 19th, and 20th of August last, at Schaffhouse, under the presidency of Dr. Stierlin, and is described as having been a highly animated one. We shall note a few of the more important papers presented; for particulars of which we are indebted to the *Archives des Sciences*.

In the section of Physics and Chemistry, M. Soret described a method for studying ultra-violet spectra. It consists in placing a thin fluorescent lamina (sulphate of quinine, *e.g.* between two glass plates) before the eyepiece of a spectroscope, where the image is formed, and observing, with sufficient inclination of the eyepiece the image of the ultra-violet spectrum then developed on the lamina. Prof. Kopp read a paper on bresiline and its derivatives. The Deacon process of manufacturing chlorine was the subject of a paper by M. Hurter, which gave rise to lively discussion. Dr. Heim, who has been observing the sounds of cascades, find they all give the note C sharp, or F.

In Geology, Dr. Schalch had a paper on the volcanic rocks of Höhgau. These are in two groups, that of basalts, and that of phonolites. They form isolated cones surrounded with thick deposits of volcanic tufa, the nature and arrangement of which indicate that the eruptions happened at successive intervals about the end of the tertiary epoch. M. Favre showed a section of the Vaudois Alps made at Pleiades, near Vevey aux Ormonts; in which he distinguishes three zones, consisting of superior Jurassic and Necomian, and different portions of Eocene, strata. Dr. Heim exhibited a new method of geological representation of a country; it consists in a series of sections, on the same scale, coloured and fixed vertically at equal distances on a geological map. He also made some observations on the zone of contact of crystalline rocks and sedimentary strata in Eastern Switzerland and the Bernese Alps. M. Lang announced the early publication, by the Alpine Club of a glacier-register, in which information will be given as to dimensions, from progress, &c., of glaciers. At the first general *séance* Prof. Heim gave a valuable *resumé* of the various theories of glacial motion. At the second, Prof. Desor presented a memoir on *morainic* landscapes, by which he denotes those indicating a former extension of glaciers. The most striking types are at the southern base of the Alps. There is discernible a zone consisting of a succession of verdant hillocks, sometimes aligned, sometimes separate; these are found to be composed of the *débris* of old formations bruised and triturated, and clearly indicating glacial action. A good example occurs at the base of Monte Campo di Fiori.

At the general opening *séance* Prof. Forel gave an account of his researches on the deep-water fauna in Lake Leman, of which he enumerates some thirty species. He had also studied the fauna of the lakes of Neuchatel, Zurich, and Constance. His conclusions are briefly these:—There are in the lakes three distinct fauna: (*a*) a littoral, extending to 15 or 20 metres depth; (*b*) a deep fauna, from 20 to 300 metres; and (*c*) a pelagic fauna. All the forms of the deep fauna have analogous or similar forms in the littoral fauna; but the converse does not hold. At the same level the deep fauna are the same. A few species found between 30 and 100 metres are not found at 300 metres, but all the types at 300 metres are found between 30 and 100 metres. There are local and seasonal differences. The deep fauna are best studied between 30 and 60 metres. In comparing different lakes the general characters of deep fauna are the same, but special characters vary.

In the section of zoology and botany, M. Bugnion described some sensitive organs found in the epidermis of Proteus and Axolotl. They are considerably developed in the former (1460 were counted in one specimen), and are disposed in linear groups of three or four along certain nerves of the head, and the lateral nerve to the end of the tail. They resemble the cyathiform organs discovered by M. Leydig in 1850, in the epidermis of fishes. Dr. Cartier gave a paper on the sensitive hairs of crocodiles.

In the medical department Prof. Karsten, of Vienna, made a communication on *necrobiosis* in which he pointed out that Bacteria, Vibriones, and microcosms, &c., are not to be regarded as organic species, properly so called; the phenomena of animal reproduction have never been observed in them. They are pathological products, which grow in the interior of vegetable or animal cells, but which do not penetrate these when once developed as parasites.

In the department of Pure Mathematics the principal paper was one by Prof. Schwarz on a new example of a continual function which does not admit of derivatives. This paper will be found *in extenso* in the *Archives*.

This is the third time in its history that the Helvetic Society has met at Schaffhouse, the former occasions having been in 1825 and 1847. The next annual session is to be held at Coire.

SCIENTIFIC SERIALS

Sitzungsberichte der Königl. Böhmischen Gesellschaft der Wissenschaften in Prag. Jan. 1871 to June 1872. (3 numbers).—Among the more valuable matter in these numbers may be noted some contributions to palæontological botany; more especially a paper by M. Feistmantel describing the various fruit-forms met with in Bohemian coal formations. (As published separately, the paper contains several excellent plates). The same author communicates also full accounts of the flora in coal-measures at the foot of the Riesengebirge, and at Merklin.—M. Dvorak describes some curious experiments on individual differences between the two eyes, and between different parts of the retina of the same eye. He shows that two non-simultaneous impressions, each affecting one eye, appear simultaneous, when the time-interval is of a certain length; this interval he measures with suitable apparatus.—In chemistry we have a note by Prof. Stolba, giving a new method of preparing borofluoride of potassium, and an account of the properties of this substance.—Dr. Weyr investigates mathematically the distance-action of electrical solenoids on material plane surfaces; and a note by M. Domalip furnishes experimental proof of certain laws deduced by M. Dub as to the dependence of magnetic moment on the dimensions of a magnetic bar.—There are also papers on the fauna of lakes in the Böhmerwald, on basaltic formations, and on several points in mineralogy and pure mathematics.

Bulletin de l'Académie Royale de Belgique, No. 8, 1873.—In this number is described a recording *meteorograph*, devised by M. Van Rysselberghe, and which seems to have some merit;

the advantage being that the readings of several different instruments can be recorded by means of a single steel graver, making traces on a varnished copper sheet. The sheet is fixed on a vertical cylinder, which rotates at equal intervals (*e.g.* every ten minutes); an electric circuit, of which the instrument to be observed forms part, is closed by the movement of the cylinder; this liberates the graver, which then gives a tracing proportional, in length, to the indication of the instrument. At each revolution the graver descends a little; thus a series of equidistant lines are obtained, the extremities of which form the curve of observations. The copper sheet is afterwards dipped in an acid and thus made ready for engraving.—M. Terby communicates some drawings made by M. Schroeter, in the end of last century, which show the configuration of the spots of Mars at that time. He finds, in these, fresh proof of the permanence of the spots.—A letter from Prof. Genocchi, of Turin, on several mathematical questions, calls forth a long report from M. de Tilly with reference to the alleged impossibility of demonstrating the postulates of Euclid by plane geometry, or by any geometrical reasoning.—We further find notes on the congelation of alcoholic liquids, (Melsens), on the motion of projectiles, on hypo-sulphurous acid, on some storms at Aartselaer in July, and other topics.

Bulletin de la Société Impériale des Naturalistes de Moscou, No. 1, 1873.—In this number there is a valuable paper of spectroscopic solar observations in 1872, by M. Bredichin. Four plates are appended, showing the spectroscopic profile of the sun from July 22 to September 10. The author's results confirm, in the main, those of Secchi.—M. Berg gives some particulars as to the successful acclimatisation of a Japan silkworm, the *Antherea Yama Mayu*, in the Baltic provinces. Cultivators were looking in this direction partly because of the difficulty of acclimatising mulberry in the north; the new animal feeds on oak leaves. One striking fact is, that some of the eggs were exposed, at times, for three days successively, to a temperature of 12° R., without apparent injury. The temperature at which the worms were kept after leaving the egg till spinning time, varied between 12° and 16° R. The entire extra-oval life of the Yama Mayu in Riga is about 16½ weeks; or 9 in the caterpillar, 6 in the chrysalis, and 1½ in the moth stages respectively. Experiments, extending over three years, have fully shown that the scheme in question is a practicable one. We have further to note a long and interesting account, by M. Wolkenstein, of certain ancient cemeteries named "Jalnikis," found on many of the hill-sides in Novgorod. The tombs are made of unhewn stones arranged in form of a rectangular cyst, which contains the skeleton. In his study of the question whether these cemeteries belonged to ancient Novgorodians, or some other people, the author is led to assign a Slavic origin.—Among the remaining papers are a note by M. Stepanoff on the development of Calyptræa, and a reply by M. Lubimoff to M. Bredichin.

Reale Istituto Lombardo di Scienze Lettere Rendiconti Fascicolo, XV, 1873.—In addition to a large quantity of historical and philosophical matter, which includes a fourth paper on Kant's philosophy, by C. Cantoni, this number contains observations of Comet II, 1873, by S. Tempel; a long paper on the polymorphism of *Pleospora Herbarum*, by Drs. Gibelli and Griffini; and also some anatomical and medical notices.

THE *Annali di Chimica applicata alla medicina* for September contains the usual number of notices on pharmaceutical preparations, &c.

American Journal of Science and Arts, October.—This number contains a description of some valuable improvements in the silt analysis of soils and clays, by Mr. Hillgard. From minute observations on the working of the elutriating apparatuses of Nöbel, Schulze, Fresenius, and others, he concludes that all determinations hitherto made with conical vessels are vitiated by irregular currents, and a kind of miniature avalanche formed by the particles. He employs a cylindrical elutriating tube, having a rotary churn attached to its base, but screened by wire from the liquid column. This has given good results.—Prof. Dana has a (continued) paper on the quartzite, limestone, and associated rock of the vicinity of Great Barrington, Berkshire Co., Mass.—Mr. May describes some experiments on the determination of lead as peroxide, and Mr. Remsen communicates a note on isomeric sulpho-salicylic acids.—Mr. Bentham's anniversary address to the Linnean Society is given; also a French Academy notice of Dr. Verneuil, who did valuable service to North American geology.—We further note accounts of various survey operations in Colorado, Sierra Nevada, Utah, &c.

Atti della Reale Academia dei Lincei Roma, Dec. 1872. This publication contains, among other papers, an interesting description, accompanied with plates, of certain human bodies found in a remarkable state of preservation in a cemetery at Ferentillo. The authors, MM. Maggiorani and Moriggia, made analyses of the soil, which abounded in salts of lime having, of course, avidity for water. The ground was porous, and readily permitted passage of vapour from one stratum to another. Scarcity of humus and good ventilation were other favouring causes. There was a popular tradition that the soil was brought from Palestine, but this is thought incorrect. The mummies were throughout invaded with sporulæ and various other parasites, which doubtless contributed to the mummification.—A long paper by M. Volpicelli offers a complete and general solution, through the geometry of situation, of the problem relating to the course of a horse over a checkered surface.—Prof. Cantoni has an article on the various modes of electrical testing (*esplorazione*) and on the influence of hypothesis in electrostatics; in which he makes some strictures on certain passages in Tyndall's little work on Electricity, referring to the existence of two fluids.—We further notice a paper by Prof. Cadet on the functions of the white nerve substance, and one by Prof. Respighi on the shower of falling stars observed November 28, 1872.

SOCIETIES AND ACADEMIES

PARIS

Academy of Sciences, Oct. 20.—M. de Quatrefages, president, in the chair.—The following papers were read:—Theory of the movement of a point attracted towards a fixed centre, by M. J. Bertrand.—On Dr. Reye's explanation of the solar spots, by M. Faye. Dr. Reye considers that the heat of a facula causes an up-rush and expansion of the superincumbent atmosphere, causing a sort of vortex through which the materials of lower strata rise, expand, cool down, and condense. M. Faye, after explaining the theory in question, argued that a very simple fact overthrows it at once. Dr. Reye's theory would make the vortex or spot *on* the sun, while the measurements of Carrington have shown that it is really *in* the sun.—Anatomical researches on the tardigrade *Edentata*, by M. P. Gervais.—M. Alph. de Candolle presented the last volume of the "Prodromus Systematis Naturalis Regni Vegetabilis."—The secretary reported on a number of papers on the *Phylloxera*.—Researches on an easy method of measuring the capacity of ships, by M. d'Avout.—Additional note to the monograph on the fish of the family of the *Symbranchidæ*, by M. C. Dareste.—On the production of galls on vines attacked by the *Phylloxera*, by M. Max Cornu.—On the reproduction of the oak *Phylloxera*, by M. Balbiani.—On the production of certain crystalline borates in the dry way, by M. A. Ditte. The paper in question described several borates of barium and magnesium, and also several double salts of the same class.—Note on the chlorovanadates, by M. P. Hautefeuille.—On the production of methylamines in the manufacture of pyroligneous products.
